#### FOREWORD

The work covered by this report was performed for the California Air Resources Board, as outlined in SwRI Proposal No. 08-23088C dated August 10, 1998. Locomotive testing was performed between August 1998 and May 1999.

The liaison with the Association of American Railroads (AAR) was Mr. Michael J. Rush, Associate General Counsel of the AAR Law Department. Three EMD model SD70MAC locomotives were provided by the Burlington Northern Santa Fe Railroad (BNSF). Mr. Mark P. Stehly coordinated BNSF's participation in the program. Three GE Model DASH9-44CW locomotives were provided by the Union Pacific Railroad (UP). Mr. Kent D. Carter of UP coordinated UP's participation in the program. A number of people from the Electro-Motive Division of General Motors Corporation (EMD) and the Transportation Systems Division of the General Electric Company (GE) were contacted on several occasions for information and advice related to the operation of their respective locomotives, and their participation and support is greatly appreciated.

This project was performed by the SwRI Department of Emissions Research of the Automotive Products and Emissions Research Division, under the supervision of Mr. Charles T. Hare, Director, and Mr. Terry L. Ullman, Manager. The Project Manager and Principal Investigator for SwRI was Mr. Steven G. Fritz, Principal Engineer. SwRI technical personnel making significant contributions to the project were Mr. Patrick M. Merritt, Senior Research Scientist; Mr. E. Robert Fanick, Senior Research Scientist; Mr. Kenneth B. Jones, Research Technologist; Mr. C. Eddie Grinstead, Research Technologist; Mr. Jeff Mathis, Senior Technician; Mr. Ernest San Miguel, Technician; and Ms. Kathy Jack, Research Assistant, all of the Department of Emissions Research; and Dr. Joe Pan, Manager of the High Resolution Mass Spectrometry Section, and Mr. Mike Dammann, Manager of the Inorganics and Radiochemistry Section, both within the Analytical and Environmental Chemistry Department of the Chemistry and Chemical Engineering Division.

#### **EXECUTIVE SUMMARY**

This project quantified exhaust emissions of two types of locomotive engines using selected diesel fuels. Locomotive exhaust emission and fuel consumption measurements were performed on six late-model locomotives: three 4,000 hp, EMD SD70MAC, and three 4,400 hp, GE DASH9-44CW. All six locomotives were provided by two participating railroads, the Burlington Northern Santa Fe (BNSF), and the Union Pacific (UP). Emission testing was performed between August 1998 and May 1999 at the Southwest Research Institute<sup>™</sup> (SwRI) Locomotive Exhaust Emissions Test Center in San Antonio, Texas. This unique facility was established in 1992 in cooperation with the Association of American Railroads (AAR).

This report contains results of regulated and selected unregulated exhaust emission measurements made on six locomotives, each operating on commercially available CARB fuel, Federal on-highway fuel with a sulfur level of 330 ppm (0.033 weight percent), and a high-sulfur (4,760 ppm) nonroad fuel. Due to the fact that the sulfur level of the "high-sulfur" fuel was higher than nonroad diesel fuel typically purchased by the railroads, a fourth fuel was also used in the three GE locomotives, which was a nonroad fuel with a sulfur level of 3,190 ppm (0.32 percent). In this report, this fourth fuel is referred to as the "0.3 percent sulfur" fuel, and is considered to be more representative of high sulfur nonroad diesel fuels used by the railroads.

Table 1 gives the average percent change in the line-haul composite emissions between test fuels for the three EMD locomotives. CARB fuel reduced composite  $NO_x$  emissions by an average of 4 percent from levels for on-highway fuel, and by an average of 6 percent from levels for high-sulfur, nonroad fuel. CARB fuel reduced composite PM emissions by an average of 3 percent from levels for on-highway fuel, and by an average of 16 percent from levels for high-sulfur, nonroad fuel. Using on-highway fuel reduced composite PM emissions by 13 percent from levels for high-sulfur, nonroad fuel.

Table 1 also gives the average percent change in the line-haul composite emissions between test fuels for the three GE locomotives. CARB fuel reduced composite  $NO_x$  emissions by an average of 3 percent from levels for on-highway fuel, and by an average of 7 percent from levels for high-sulfur, nonroad fuel. These results are very consistent with the  $NO_x$  response observed for the EMD locomotives.

FUEL CHANGE	Percent change in Average Line-Haul Composite Emissions <sup>a</sup>							
	НС	со	NO <sub>x</sub>	РМ

CARB vs 0.3% Sulfur °	+1%	- 3 %	- 5 %	- 27 %				
On-Hwy vs 0.3% Sulfur <sup>°</sup>	+ 4 %	- 2 %	- 2 %	- 25 %				
Notes: a - EPA Line-Haul duty cycle weighted emissions. b - 4,670 ppm sulfur nonroad fuel, EM-2664-F c - 0.3% Sulfur fuel = 3,190 ppm sulfur, EM-2708-F								

# TABLE 1. AVERAGE CHANGE IN REGULATED LOCOMOTIVE EXHAUSTEMISSIONS BETWEEN TEST FUELS

Using the 0.3 percent sulfur nonroad fuel as the basis of comparison, CARB fuel reduced composite  $NO_x$  emissions for the GE locomotives an average of 5 percent. Onhighway fuel reduced composite  $NO_x$  emissions by 2 percent compared to levels from the 0.3 percent sulfur, nonroad fuel. Table 1 also shows that switching from the high-sulfur (0.476 percent sulfur) fuel to the 0.3 percent sulfur fuel reduced the average composite  $NO_x$  emissions from the GE locomotives by 2 percent.

In the GE locomotives, using CARB fuel reduced the average composite PM emissions by an average of 3 percent compared to on-highway fuel, and by an average of 39 percent compared to high-sulfur, nonroad fuel. Using on-highway fuel, average composite PM emissions were reduced by 38 percent compared to high-sulfur, nonroad fuel. Using the 0.3 percent sulfur nonroad fuel as the basis of comparison, CARB fuel reduced composite PM emissions an average of 27 percent compared to 0.3 percent sulfur, nonroad fuel reduced composite PM emissions by 25 percent compared to the 0.3 percent sulfur, nonroad fuel.

For the two locomotive models tested, switching from the high-sulfur, nonroad diesel fuel to CARB fuel reduced the average NOx emissions by 6-7 percent, which corresponds to a reduction of about 0.8 g/hp-hr. This  $NO_x$  reduction is similar to that observed for on-highway diesel engines. No formal statistical analysis of the data was performed by SwRI, but test results were provided to ARB and the AAR for their analysis.

Sulfate analysis of the PM samples indicated that the PM reduction with CARB fuel was largely attributable to the reduced sulfur content of the fuel, and on a g/hp-hr basis, the PM response was essentially the same for each locomotive model. Figure 1 shows the effect of fuel sulfur content on the PM emissions from the two models of locomotives tested. HC and CO emissions were relatively insensitive to the fuels tested, as were smoke emissions. Regardless, the ARB and AAR statistical analyses of the data should be used for the final determination of statistically significant changes in the emissions between fuels.

FIGURE 1. EFFECT OF TEST FUEL SULFUR CONTENT ON PM EMISSIONS

#### I. INTRODUCTION

This project quantified the exhaust emissions from two types of locomotive engines using selected diesel fuels. Locomotive exhaust emission and fuel consumption measurements were performed using three fuels on six locomotives: three high-power, late-model EMD, and three high-power, late-model GE locomotives were tested. A fourth fuel was added after the program began, and was tested in the three GE locomotives. Locomotive selection was the responsibility of the participating railroads, which were the Burlington Northern Santa Fe (BNSF), and the Union Pacific Railroad (UP).

Testing was performed at the Southwest Research Institute (SwRI) Locomotive Exhaust Emissions Test Center in San Antonio, Texas. This unique facility was established in 1992 in cooperation with the Association of American Railroads (AAR), and is the only non-OEM facility capable of performing locomotive exhaust emission tests. To date, over 50 locomotives have been tested by SwRI in work for the AAR, the OEM's, and the U.S. EPA.

A Technical Oversight Committee composed of representatives from ARB, BNSF, UP, and the AAR was formed to provide SwRI with technical direction throughout the project's duration.

#### II. TECHNICAL APPROACH

Locomotive exhaust emission tests for this project were performed by SwRI at the Locomotive Exhaust Emissions Test Center in San Antonio, Texas. This facility was established in August 1993 in cooperation with the AAR and what was then the Southern Pacific Transportation Company (SP).

Presented below is an overview of the technical approach used to conduct locomotive exhaust emissions testing. Included is a description of the locomotives selected for testing, engine power measurement, fuel consumption measurement, the test fuels used in this program, exhaust emissions test procedures, analytical procedures, particulate measurement procedures, and smoke opacity test procedures.

#### A. <u>Test Locomotives</u>

Selection of the locomotives for emission testing was the responsibility of the BNSF and UP railroads. The locomotives selected for this study represented current production locomotives covering 1995 and 1996 model years.

Three GE locomotives were provided by UP, and three EMD locomotives were provided by BNSF. Table 2 summarizes the road number, locomotive date of manufacture, locomotive serial number, engine model, and engine serial number for each locomotive.

The line-haul locomotives used in this work were equipped with the "dynamic brake" feature in which the electric motors used for traction can be reverse-excited to become generators to slow the train. The electrical power generated by braking is dissipated in resistance grids contained on the locomotive. The test locomotives, with the self-load feature, were set to dissipate the main alternator power directly into these "dynamic brake" resistance grids, allowing static test of the locomotive.

#### B. Engine Power Measurement

The goal of "power measurement" is to establish the power produced by the engine, referred to as flywheel or "gross" power, and does not include parasitic power used to support the engine itself, such as fuel pumps, water pumps, etc. The bulk of the engine's flywheel power is converted to electrical power to drive the traction motors and the

remainder is used for accessory loads. There are subtle differences between the locomotive manufacturers in their approach to quantifying flywheel power. The primary differences arise in alternator efficiencies quoted by the locomotive manufacturers, and approaches in accounting for various accessory loads. Gross power represents the sum of "traction power" plus "auxiliary power". For these tests, observed (uncorrected) gross power was used for computing brake-specific emissions.

TABLE 2. LOCOMOTIVES TESTED

Gross power for the GE locomotives was recorded from the onboard computer display. Recording the gross power using the on-board computer is a deviation from the EPA locomotive test procedure for locomotives, which calls for direct measurement of electrical power with an NIST-traceable accuracy of better than two percent. EPA also requires that the specified alternator efficiency for each test point be given along with the basis for determining the efficiency.<sup>1</sup> Due to the fact that the objective of this study was to document emissions using different fuels on the same locomotive, the absolute accuracy of gross power measurement was of secondary concern, and any small inaccuracies in the measured power would be applied uniformly to emission results for a given locomotive.

<sup>&</sup>lt;sup>1</sup> CFR, Title 40, Part 92, §92.106 "Equipment for loading the engine."

Like the GE locomotives, the on-board computer display was used to record the traction power from the EMD locomotives. Accessory loads from the auxiliary generator, air compressor, traction motor blower, inertial separator blower, radiator cooling fans, and TCC blower were computed based on published EMD load box test procedures.

Power and fuel rates are reported as observed values. Observed gross power was used to report brake-specific exhaust emissions in g/hp-hr. However, corrected brake-specific fuel consumption (BSFC) values were reported by applying published EMD and GE correction factors for ambient air temperature, barometric pressure, fuel heating value, fuel temperature, and fuel specific gravity.

#### C. Fuel Consumption Measurement

Diesel fuel consumption rate was measured on a mass basis, using a mass flow meter adapted from laboratory use at SwRI. The system was equipped with a heat exchanger to control fuel supply temperature to 90±10°F. Hot return fuel that normally returns to the locomotive's on-board fuel tank was cooled before returning to the fuel measurement reservoir ("day" tank) to assure consistent fuel supply temperature to the engine.

#### D. <u>Test Fuels</u>

Four fuels were included in this study, and selected properties of the fuels are summarized in Table 3. Sixteen thousand gallons of "CARB" fuel was provided by Equilon (under separate agreement between CARB and Equilon), and stored on site in a rail tank car provided by BNSF. The CARB fuel was a blend of 8,000 gallons of commercially available CARB-approved fuel from the Texaco refinery in Los Angeles, California, plus another 8,000 gallons of commercially-available CARB-approved fuel from the ARCO refinery in South Gate, California. Both fuels were delivered to the SwRI Locomotive Test Center by truck, and the fuels were mixed in a single tank car. The properties of the CARB fuel were considered by ARB to be representative of commercially available on-highway fuel sold in California.

Federal "on-highway" fuel was a commercially available product purchased by Equilon from Sun Coast Resources, Inc. in Houston, Texas. Sixteen thousand gallons of this fuel were stored on site in a second rail tank car provided by BNSF. "High-sulfur, nonroad" fuel was also provided by Equilon, and was purchased from the Costal Refining and Marketing, Inc. refinery in Corpus Christi, Texas. This too was a commercially available product. Sixteen thousand gallons of this fuel was stored in a third rail tank car, which was provided by UP. This fuel had a relatively high sulfur content of 4,760 ppm (0.476 weight percent).

Locomotive testing began in September 1998 with three fuels (CARB fuel, onhighway fuel, and high-sulfur, nonroad fuel). Two EMD model SD70MAC locomotives were tested with these three fuels. By the time testing of the first GE locomotive was scheduled, the railroads expressed concern over the unusually high sulfur content (4,760 ppm) of the high-sulfur, nonroad fuel (SwRI fuel code EM-2664-F).

The railroad's position was that this sulfur level was not representative of railroad fuel, and that a fuel sulfur level of approximately 3,000 ppm was more appropriate. A fuel sulfur content of 3,000 ppm would be the mid-point of the range EPA specified, 2,000 ppm to 4,000 ppm sulfur content, for certification testing.<sup>2</sup> In response to the railroad concerns, ARB requested that SwRI blend a fourth test fuel with a target sulfur level of 3,000 ppm.

The approach taken by SwRI was to blend 5,000 gallons of the existing 4,760 ppm sulfur fuel with 3,300 gallons of a blend fuel purchased from Specified Fuels & Chemicals. The blend fuel was selected such that except for sulfur, the remaining fuel properties were similar to the 4,760 ppm sulfur fuel. The fourth test fuel was blended in a fourth tank car that SwRI had available at the test site.

An analysis of the fourth test fuel was performed, and the results are included in Table 3 (SwRI fuel code EM-2708-F), along with the properties of the original three test fuels. The fuel sulfur content of the fourth fuel, the "0.3 percent sulfur nonroad fuel" was 3,190 ppm. Table 3 also shows the specifications for locomotive emissions test fuel given in the Code of Federal Regulations, Title 40, Section 92.113. Although it was not the objective of this program to include a fuel meeting EPA specifications, the 0.3 percent sulfur nonroad fuel met the EPA requirements.

Triplicate emission tests using the fourth fuel were initiated with the first GE locomotive, UP No. 9715, and this fuel was used in addition to the other three fuels. Therefore, a total of twelve tests (triplicate tests on four fuels) were run on UP No. 9715.

<sup>&</sup>lt;sup>2</sup> 40 CFR, §92.113 "Fuel Specifications".

Adding the fourth test fuel added two test days to the schedule for each of the three GE locomotives. Due to budget constraints, ARB dropped unregulated emissions measurement when using the fourth fuel, and when the third EMD locomotive was tested later in the project, only the three original fuels were used, because it was desired to be consistent with the first two EMD locomotives, tested with only the three original fuels.

Included with the unregulated emissions analysis planned for this program were measurements for trace quantities of metals within the exhaust particulate. Therefore, an ASTM D-5185 metals analysis of the test fuels was performed to quantify trace quantities of metals that may have been present in the test fuels. The metals of interest were provided by ARB, and these were the same metals of interest for selected exhaust PM samples. ASTM D-5185 essentially outlines a procedure that uses an inductively coupled plasma (ICP) technique for lubricating oil metals analysis. However, for this work, the procedure was applied to diesel fuels.

Table 4 shows that the only metal detected in the test fuels was trace quantities of lead, which was present in both the on-highway fuel and the 0.3 percent sulfur nonroad fuel, in levels just above the detection level of 1 ppm. Other values given in Table 4 indicate that levels of these metals were below the detection limit. The detection limits given were established with readily available calibration standards. Although chloride was included for PM analysis, the ICP technique used to analyze the fuel could not be used for chloride.

#### E. <u>Regulated Exhaust Emissions Test Procedures</u>

SwRI used the Federal Test Procedure (FTP) for locomotives as detailed in Title 40 of the U.S. Code of Federal Regulations (CFR), Part 92, Subpart B, to measure the regulated emissions of hydrocarbons (HC), carbon monoxide (CO), oxides of nitrogen ( $NO_x$ ), particulate matter (PM), and smoke opacity. Deviations from the FTP included using test fuels that did not meet EPA specifications, and using the locomotive's on-board computer display for gross power instead of directly measuring the main alternator voltage and current, as was described earlier in Section II.B of this report.

SwRI ran triplicate FTP tests for emissions on each locomotive for each of the fuels selected. The order of fuels tested was randomized. In accordance with the FTP, emissions of HC, CO,  $NO_x$ , and PM were measured for each throttle notch, along with smoke opacity. In addition, switch cycle and line-haul weighted composite emission levels were calculated.

#### 1. Test Modes and Repeat Testing

Following the FTP, SwRI measured steady-state emissions (HC, CO,  $NO_x$ , and particulate), smoke opacity, fuel consumption, and power at each throttle notch, starting at idle. Brake-specific emissions were computed for each throttle notch, along with duty-cycle weighted composite emissions.

#### 2. Gaseous Emissions Sampling

The gaseous sample probe was designed using specifications in 40 CFR §86.310-79. Gaseous emissions were sampled directly from within the exhaust stack extension installed on the roof of the locomotive. A heated line was used to transfer the raw exhaust sample to the emission instruments for analysis. Measured gaseous emissions included HC, CO, carbon dioxide (CO<sub>2</sub>), oxygen (O<sub>2</sub>), and NO<sub>x</sub>.

HC concentrations in the raw exhaust were determined using a Rosemount Analytical model 402 heated flame ionization detector (HFID), calibrated on propane. Following diesel emission measurement protocols in the FTP, steady-state  $NO_X$ concentration in the raw exhaust was measured with a chemiluminescent instrument.  $NO_X$ correction factors for engine intake air temperature and humidity were applied as specified by EPA in the FTP. Concentrations of CO and  $CO_2$  in the raw exhaust were determined by non-dispersive infrared (NDIR) instruments.

#### NO<sub>x</sub> Correction Factors

The EPA  $NO_x$  correction factor given in Title 40 of the Code of Federal Regulations 92.132(d) is:

$$KNO_{x} = (K) \times (1 + (0.25 \times (\log K)^{2})^{1/2})$$
 (Eq. 1)

 $KNO_x$  is intended to be the total correction applied to the observed  $NO_x$  mass emission rate. The "K" term is comprised of two factors, a factor for ambient air humidity correction (K<sub>H</sub>), and a factor for ambient air temperature correction (K<sub>T</sub>).

$$\mathbf{K} = (\mathbf{K}_{\mathrm{H}}) \mathbf{x} (\mathbf{K}_{\mathrm{T}})$$
(Eq. 2)

From an engineering standpoint, the  $K_H$  and  $K_T$  terms in Equation No. 2 represent the corrections for humidity and temperature that were based on available data at the time the locomotive rule was published in April 1998.

The ambient air temperature correction factor,  $K_T$ , was included in the Locomotive Rule to prevent certificate applicants from deliberately running certification tests at ambient temperatures well below 86°F in an effort to achieve lower NO<sub>x</sub> levels. The minimum ambient air temperature allowed is 45°F. On days cooler than 86°F, it is expected that roots-blown EMD engines and new locomotives equipped with separate-circuit charge air cooling would have lower observed NO<sub>x</sub> levels than locomotives that use jacket water charge-air cooling systems. The latter are less sensitive to the effects of ambient air temperature within the range of interest (45°F to 105°F).

Ideally, the  $K_T$  factor would correct the observed NO<sub>x</sub> level to a level expected with an ambient air temperature of 86°F. However, for ambient air temperatures at or above 86°F, the Locomotive Rule fixes  $K_T = 1.0$ , specifying that no temperature correction is allowed. For ambient air temperatures below 86°F, the value of  $K_T$  is adjusted in proportion to the difference between the intake manifold air temperature observed during the test and that observed when ambient temperature was actually 86°F, for the same notch position. Unfortunately, EMD and GE have not published data for the intake manifold air temperature for an 86°F ambient for each throttle notch. In addition, most of the ARB locomotive tests were run at ambient air temperatures greater than 86°F, so no  $K_T$  correction is applicable for those tests, per the Locomotive Rule. Therefore, in the absence of available data from the manufacturers,  $K_T$  was set to 1.0 for all test data reported in the ARB fuel-effects study. If manufacturer's data becomes available at a later date, the affected locomotive test data could be reprocessed to include the  $K_T$  correction.

Ambient air humidity levels significantly affect  $NO_x$  levels from diesel engines. The humidity portion of the  $NO_x$  correction factor,  $K_H$ , as outlined in §92.132(d), was used in this study.

#### 3. Particulate Emissions Sampling

Particulate emissions were measured at each test point using a "split then dilute" technique, in which a portion of the raw locomotive exhaust was "split" off of the total flow and mixed with filtered air in an 10-inch diameter dilution tunnel. The split sample was transferred to the dilution tunnel through a 2-inch diameter stainless steel tube that was insulated and electrically heated to 375°F. The dilution tunnel was located at ground level, next to the locomotive, as shown in Figure 2.

FIGURE 2. PARTICULATE DILUTION TUNNEL

The dilute exhaust stream in the dilution tunnel was then sampled using probes shown in Figure 3. Particulate was accumulated on 90 mm Pallflex T60A20 fluorocarbon-coated glass fiber filters at a target filter face velocity of 70 cm/s. The filters were mounted in stainless steel filter holders and connected to the dilution tunnel. Sampling time for particulate measurement was typically five minutes. However, this sample time was shortened when observed pressure differential across the filter sets increased beyond a predetermined value of 40 inches  $H_2O$ . Particulate filters were preconditioned and weighed before and after test following EPA procedures in the FTP. The particulate mass emission rate was computed using the increase of mass on the filters, the volume of dilute exhaust drawn through the filters, and dilution air and raw exhaust flow parameters.

FIGURE 3. PARTICULATE SAMPLE PROBES LOCATED WITHIN DILUTION TUNNEL

#### 4. Smoke Opacity Test Procedures

Smoke opacity was measured using a modified U.S. Public Health Service (PHS) full-flow opacity meter (smokemeter) mounted above the locomotive exhaust stack. This smokemeter used standard PHS smokemeter optics and electronics, but was modified to a 40-inch diameter to accommodate large exhaust plume diameters. The construction,

calibration, and operation of the smokemeter followed protocols established by EPA for certification testing of locomotive engines as given in the FTP.

Figure 4 shows the smokemeter assembly installed above the exhaust stack extension of a locomotive. The smokemeter was aligned with the long axis of the rectangular exhaust stack. The through-exhaust path length for the single-stack turbocharged locomotives was approximately 37 inches (as determined by the dimensions of the exhaust stack extension). The center of the light beam was positioned  $5\pm1$  inches above the outlet of the exhaust stack extension.

FIGURE 4. SwRI SMOKEMETER INSTALLED ON A LOCOMOTIVE

#### 5. Locomotive Test Sequence

Upon delivery of the locomotive to the test site in San Antonio, a self load test was performed to ensure that the locomotive was producing the expected power. The test fuel supply, exhaust stack extension, and smokemeter ring were then installed. A quick test at each of the throttle notches was performed to determine the appropriate instrument ranges to use for each notch.

The test sequence used for locomotive testing is specified in the FTP. Before emission testing was started, the engine was brought to operating temperature. Generally, this involved operating the locomotive at Notch 8 for at least 15 minutes. After the warm-up period, testing began with idle. The FTP calls for a single test point representing dynamic brake (DB) operation. Like the definition of "idle," there may be several options for defining a single DB test point for emission measurements. For this program, tests were performed at the dynamic brake engine operating condition, DB-2.

#### F. Unregulated Exhaust Emission Test Procedures

Selected unregulated emissions were measured at all throttle notches for selected locomotives and fuels. The ARB requested that the following unregulated emissions be measured:

- Benzene
- 1,3-Butadiene
- Formaldehyde
- Acetaldehyde
- Acrolein
- Polycyclic aromatic hydrocarbons (PAH) (both gas phase and PM phase)
- Volatile Organic Fraction of total particulate (VOF)
- Metal Particulate
- Sulfates
- Soluble organic fraction (SOF) of particulate

Presented below is a brief discussion of the analytical methods used for sampling and analyzing the unregulated emissions.

**1. Benzene and 1,3-butadiene** - Analyses of benzene in the dilute exhaust was made using a Hewlett-Packard 6890 gas chromatograph (GC), and a flame-ionization detector (FID). The GC was set up at the locomotive test site to facilitate rapid analysis. The analytical setup included a 2 meter pre-column of 0.25 mm I.D. deactivated fused silica, followed by a capillary analytical column (DB-5<sup>®</sup>, 30 m x 0.25 mm, 0.25 Fm film thickness). The dilute sample was injected via a 5 mL gas sample loop which was maintained at 120EC. The column oven temperature profile began at -80EC and progressed to 250EC.

A Perkin-Elmer model 3920B GC with a FID was set up at the locomotive test center for analysis of 1,3-butadiene. It is important to analyze dilute exhaust samples quickly as butadiene is a reactive species, and the sample concentration can decrease within hours. This GC employed a nine-foot by 1/8-inch stainless steel column packed with 80/100 Carbopak C<sup>®</sup> coated with 0.19 percent picric acid. The carrier gas was helium, at a flow rate of 27 mL per minute. The column was maintained at 40°C for the entire analysis.

**2. Formaldehyde, acetaldehyde and acrolein** - To collect aldehydes and ketones, samples of the diluted exhaust and background air were passed through traps containing silica impregnated with 2,4-dinitro-phenylhydrazine (DNPH). Any aldehyde or ketone present in the sampled gas reacted quickly with the DNPH to form a stable derivative. These derivatives were subsequently extracted from the trap by elution with ultra-pure acetonitrile. Analysis of the samples was performed using a high performance liquid chromatograph (HPLC) with ultra-violet (UV) detection.

**3. PAH** - Gas-phase polycyclic aromatic hydrocarbons (PAH) were collected using PUF/XAD traps. Particulate-phase PAHs were collected using a second pair of 90mm filters that were taken simultaneously with the first set of 90mm PM filters, used to establish PM mass emissions. Target analytes are given in Table 5. The PAH detection limit was approximately 5 ng PAH/sample, assuming no significant amount of interference was present in sample extract after cleanup.

Table 5 also lists the PAH compounds on EPA's "211b" target list. The "211b" list comes from EPA's gasoline and diesel motor vehicle fuel additives registration regulations, detailed in Title 40 CFR, Part 79.

The particulate-laden filters were spiked with a mixture of surrogate solution which contained the deuterated compounds fluorene-d10 and terphenyl-d14, at a final concentration of 1.0 ng/FI. They were then Soxhlet extracted for 18 hours using a solvent system that contained ethanol (30 percent) and toluene (70 percent). The extracts were blown down and exchanged into hexane. A cleanup procedure was applied which consisted of sulfuric acid wash and gravity chromatography. A cleanup standard of anthracene-d10 at 1.0 ng/FI was added to monitor the cleanup procedure. The column of the chromatograph was packed with silica gel impregnated with sulfuric acid. The PAHs were eluted out of the column with a solvent system that contained 60 percent dichloromethane (DCM) and 40 percent hexane. The cleaned up extracts were then blown down to 100  $\mu$ L. A mixture of recovery standards was spiked to the final extracts prior to GC/MS selected ion monitoring analysis. The recovery standards included acenaphthene-d10, pyrene-d10, and benzo(e)pyrene-d12 at a final concentration of 1.0 ng/FI on column.

The PUF/XAD-2 (gas-phase PAH) traps were extracted, cleaned up, and analyzed the same way as the filters, except that the extraction solvent was DCM. In addition to the recovery standards, a mixture of fifteen deuterated internal standards was added at the time of extraction, to result in a final concentration of 1.0 ng/FL on column. Finally, a matrix

of spike samples and duplicates was analyzed in which all target compounds were spiked at a final concentration of 1.0 ng/FL on column.

PAH Compound	CARB Locomotive Study	EPA 211b Target List

Dibenz(a,h)anthracene	X	Х
Benz(g,h,i)perylene	Х	Х

TABLE 5. PAH TARGET COMPOUND LIST

**4. Volatile Organic Fraction of Total Particulate (VOF)** - Direct filter injection gas chromatography (DFI/GC) was used to measure the volatile organic fraction (VOF) of diesel particulate emissions using the same 90mm Pallflex T60A20 filter collection media used for particulate mass determination. The contribution of unburned lubricating oil to VOF was determined by an interpretive procedure based on comparison of simulated distillation boiling point distribution of a fresh lubricating oil sample to that of the volatile organic fraction for the total particulate. Therefore, an external standard of locomotive

engine lubricating oil was used to quantify the lubricating oil contribution to the VOF. A major advantage of the DFI/GC method over other methods is that a solvent extraction procedure, which has inherent handling errors, is not required.

Analysis by DFI/GC used a Perkin Elmer Model 8500 gas chromatograph (GC) equipped with a uniquely designed filter injection system and a flame ionization detector (FID). Folded filters were placed into the injector, which was subsequently inserted into a cool zone of the GC to allow any oxygen in the system to be purged without losing any sample by desorption. When all oxygen had been purged from the system, the injector was pushed into a heated zone of the GC inlet, where the volatile materials were desorbed and deposited onto the cool column. The GC temperature program then separated the volatilized compounds by boiling point. These compounds were then detected with an FID.

**5. Metal Particulate** - 90mm Nucleopore filters were analyzed to determine the weight fraction of metals present in the total PM. This information was then used to compute the mass emission rate of metals in the exhaust. Sample preparation was conducted as follows: each particulate-laden filter was cut in half and placed in a precleaned, Teflon PFA microwave digestion vessel. Ten milliliters of trace metals grade concentrated nitric acid was added to each vessel. The vessel was capped and placed in a CEM MARS5 Microwave Accelerated Reaction System. "Filter XP1500" was the microwave method that was employed. In this method, a power of 1200W was applied to ramp the temperature of the vessel contents to 240EC in 10 minutes; and then it was held at that temperature for an additional 10 minutes. Once the vessels cooled, the samples were transferred to centrifuge tubes and brought up to a final volume of 50 milliliters with deionized water. The digests of the samples were then analyzed for metals using inductively coupled plasma atomic emission spectrometry (ICP-AES) for all elements except mercury, which was run using cold vapor atomic adsorption (CVAA).

6. Sulfates - To isolate the specific effect of fuel sulfur content on PM, sulfate analysis was performed.  $SO_3$  in the dilute engine exhaust reacts rapidly with water in the exhaust to form sulfuric acid aerosols. The aerosols grow to a filterable size range and are collected as a particulate on the PM filters, along with sulfate salts.

The sulfate portion of the total particulate mass accumulated on 90 mm Pallflex T60A20 filter media was quantified using ion chromatography. Any sulfuric acid on the filter was converted to ammonium sulfate by exposure to ammonia vapor in a conditioning chamber. The soluble sulfates were then leached from the filter with a measured volume

of 60 percent isopropanol (IPA) and 40 percent water solution. An aliquot of this extract was injected via autosampler into an ion chromatograph. Anions were separated by the analytical column, and passed through a conductivity detector. The retention time on column provided identification of the anion and the intensity of the signal corresponded to the concentration detected.

The range of the method is quite broad. The instrument is capable of detecting sulfate at levels lower than 0.02 Fg/mL and up to approximately 8 Fg/mL. The sensitivity of this method, however, is limited by the background level of sulfate contained in the Pallflex T60A20 filter media, which is on the order of 0.2 Fg/mL. The values measured for the samples must have the filter background value subtracted. Thus, low sulfate levels in the exhaust may be obscured by correcting for background sulfate present in the filter media. The precision (expressed as coefficient of variation) of the method on the 10 micro siemen scale (which is typically used) with nine observations of a 0.6 Fg/mL standard, is 4.3 percent.

Assuming a detection limit of 0.2  $\mu$ g/mL in solution, back-calculating for the conditions used for locomotive testing (different power settings), the range of detection limit for this test work is shown in Table 6.

REPRESENTATIVE DETECTION LIMIT RANGES FOR SULFATE						
mg/hr mg/bhp-hr mg/lb fuel						
37 - 330 0.1 - 3.5 0.2 - 1.5						

TABLE 6. REPRESENTATIVE DETECTION LIMIT RANGES FOR SULFATE

#### 7. Soluble Organic Fraction

The soluble portion of the organic fraction of total particulate (SOF) was determined by extracting a portion of the particulate-laden 90 mm Pallflex T60A20 PM filter, using a micro-soxhlet apparatus in accordance with ARB's "Test Method for Soluble Organic Fraction (SOF) Extraction" dated April 1989. Resulting SOF levels were determined using a filter weight loss method. The only variation from the ARB procedure was that the extraction was performed on a 40 percent "pie slice" of the 90 mm PM filter, while the ARB procedure calls for using a 47 mm diameter filter, and extracting the whole filter. This variation should not adversely affect the SOF results.

#### **III. REGULATED EMISSION TEST RESULTS**

**A.** <u>EMD</u> - Table 7 gives average EPA line-haul duty cycle weighted, or composite, emissions of HC, CO,  $NO_x$ , and PM for triplicate tests for the three EMD locomotives tested. Individual test summaries for each of the three EMD locomotives are given in Appendices A through C.

Locomotive / Fuel	Average EPA Line-Haul Composite Emissions <sup>a</sup> , g/hp-hr					
	HC	со	NO <sub>x</sub>	РМ		
BNSF No. 9693

Nonroad High Sulfur fuel	0.32	1.1	12.2	0.29		
Notes: a - Average of three tests on each	fuel.					

TABLE 7. EMD SD70MAC EMISSIONS SUMMARY

On a given fuel, all three EMD locomotives had similar composite  $NO_x$  and HC levels, but the CO and PM levels were not consistent between locomotives. The CO and PM levels measured for BNSF No. 9696 were similar to levels for earlier tests performed by SwRI for the EPA in 1995 on BN No. 9457, which was also an EMD SD70MAC.<sup>3</sup> Results from BNSF No. 9696 show that line-haul composite  $NO_x$  and HC emissions are

<sup>&</sup>lt;sup>3</sup> Fritz, S. G., "Emissions Measurements - Locomotives," SwRI Final Report No. 5374-024, EPA Work Assignments 1-4 and 2-4, Contract No. 68-C2-0144 (August 1995).

consistent with the first two locomotives, but CO and PM levels were much lower, on the order of half the level measured on the first two locomotives. Note that each of the three EMD locomotives tested in this work had new fuel injectors installed prior to testing at SwRI.

Table 8 gives the average percent change in the line-haul composite emissions between test fuels. For the three EMD locomotives, CARB fuel reduced composite  $NO_x$  emissions by an average of 4 percent from levels for on-highway fuel, and by an average of 6 percent from levels for high-sulfur, nonroad fuel. SwRI did not perform a formal statistical analysis of the emissions results, because test results were provided to ARB and the AAR for their own statistical analyses.

Table 7 shows that although the average level of composite PM emissions varied considerably between the three EMD locomotives on a given fuel, the PM responses to fuel changes were comparatively consistent. As reported in Table 8, CARB fuel reduced composite PM emissions by an average of 3 percent from levels for on-highway fuel, and by an average of 16 percent from levels for high-sulfur, nonroad fuel. Using on-highway fuel reduced composite PM emissions by 13 percent from levels for high-sulfur, nonroad fuel. The role of fuel sulfur in PM emissions is discussed in Section II.F.6 of this report.

TABLE 10. GE DASH9-44CW EMISSIONS SUMMARY

Table 11 gives the average percent change in the line-haul composite emissions between test fuels for the three GE locomotives. CARB fuel reduced composite  $NO_x$  emissions by an average of 3 percent from levels for on-highway fuel, and by an average of 7 percent from levels for high-sulfur, nonroad fuel. These results are very consistent with the  $NO_x$  response observed for the EMD locomotives.

Using the 0.3 percent sulfur nonroad fuel as the basis of comparison, CARB fuel reduced composite  $NO_x$  emissions an average of 5 percent from levels for 0.3 percent sulfur, nonroad fuel. On-highway fuel reduced composite  $NO_x$  emissions by 2 percent compared to levels from the 0.3 percent sulfur, nonroad fuel. Table 11 also shows that switching from the high-sulfur (0.476 percent sulfur) fuel to the 0.3 percent sulfur fuel reduced the average composite  $NO_x$  emissions from the GE locomotives by 2 percent.

Composite PM emission levels for the three GE locomotives on a given fuel had less variation than was observed for the EMD locomotives. Table 11 gives the average percent difference in the weighted emissions between test fuels for the three GE locomotives. Using CARB fuel reduced the average composite PM emissions by an average of 3 percent compared to on-highway fuel, and by an average of 39 percent compared to high-sulfur, nonroad fuel. Using on-highway fuel, average composite PM emissions were reduced by 38 percent compared to high-sulfur, nonroad fuel.

FUEL CHANGE	Percent change in Average Line-Haul Composite Emissions <sup>a</sup>							
	НС	со	NO <sub>x</sub>	РМ				
CARB vs On-Hwy	- 4 %	- 1 %	- 3 %	- 3 %

## TABLE 11. AVERAGE CHANGE IN REGULATED GE LOCOMOTIVE EXHAUSTEMISSIONS BETWEEN LOCOMOTIVE TEST FUELS

Using the 0.3 percent sulfur nonroad fuel as the basis of comparison, CARB fuel reduced composite PM emissions an average of 27 percent compared to 0.3 percent sulfur, nonroad fuel, and using on-highway fuel reduced composite PM emissions by 25 percent compared to the 0.3 percent sulfur, nonroad fuel. Table 11 also shows that

switching to the 0.3 percent sulfur fuel from the high-sulfur (0.476 percent sulfur) fuel reduced the average PM emissions from the GE locomotives by 17 percent.

Table 12 summarizes the smoke opacity emissions for the three GE locomotives. Summaries of the individual smoke test results for the three GE locomotives are given in Appendices D through F. No statistical analysis of the smoke test results was performed by SwRI, but inspection of the results given in Table 12 suggests that there was no major change in smoke opacity results between the four fuels in the three GE locomotives.

## TABLE 12. GE DASH9-44CW SMOKE OPACITY SUMMARY

### **IV. UNREGULATED EMISSION TEST RESULTS**

This section of the report presents results of unregulated emission measurements performed on each of the locomotives. Note that unregulated emissions were measured during one of three test runs on each of the three originally planned test fuels. Unregulated emissions were not measured with the 0.3 percent high-sulfur fuel.

## A. Benzene and 1,3-Butadiene

Benzene and 1,3-butadiene emissions were measured on the first two of each of the EMD and GE locomotives, and the results are given in Appendix G. Table 13 and Figures 5 and 6 summarize the EPA line-haul duty-cycle weighted (composite) values for benzene and 1,3-butadiene emissions. In general, no specific trend in benzene or 1,3butadiene emissions appeared as a function of fuel type for either the EMD or the GE locomotives. However, the GE locomotive engines had benzene emission levels roughly twice as high as the EMD locomotive engines, and 1,3-butadiene emission levels about 40 percent higher than the EMD engines.

	EPA Line-Haul Composite Emissions

FIGURE 5. AVERAGE COMPOSITE BENZENE EMISSIONS

FIGURE 6. AVERAGE COMPOSITE 1,3-BUTADIENE EMISSIONS

### B. Formaldehyde, Acetaldehyde, Acrolein

Formaldehyde, acetaldehyde, and acrolein emissions were measured on the first two of each of the EMD and GE locomotives, and the results are given in Appendix H. Table 14 and Figures 7 through 9 summarize the EPA line-haul composite values. In general, no trend in formaldehyde, acetaldehyde, or acrolein emissions appeared as a function of fuel type for either the EMD or the GE locomotives.

FIGURE 9. COMPOSITE ACROLEIN EMISSIONS SUMMARY

## C. PAH

PAH emissions were measured on the first two of each of the EMD and GE locomotives, during one of the three tests on each of the three original test fuels. No PAH measurements were made while operating on the 0.3 percent sulfur nonroad fuel. Detailed PAH results are given in Appendix I, expressed on a mass emission rate basis (milligrams per hour), for each of the four locomotives, on each of the three fuels, at each throttle notch, for each of the nineteen PAH compounds, in both gas-phase and PM-phase. There is extensive PAH data included in Appendix I, and numerous ways to analyze and present the data. Spreadsheets of the PAH data were provided to ARB for analysis. For summary purposes, the individual throttle notch results were used to compute EPA line-haul composite PAH emission rates, expressed on a brake-specific basis in units of micrograms per horsepower-hour ( $\mu$ g/hp-hr). These results are given in Table 15. Also included in Table 15 is a summation of the total brake-specific PAH emissions for each locomotive on each test fuel, plus a separate summation of the vapor-phase PAH compounds, and the PM-phase PAH compounds. More than one significant figure is used in parts of Table 15 for completeness, but does not imply accuracy beyond one significant figure.

#### TABLE 15. EPA LINE-HAUL COMPOSITE PAH EMISSIONS

Figures 10 and 11 show the total composite PM-phase PAH and gas-phase PAH emissions, respectively.

FIGURE 11. COMPOSITE GAS-PHASE PAH EMISSIONS

Several observations can be made from the PAH results given in Table 15, and in Figures 10 and 11. The total composite PAH emissions for the GE locomotives were roughly 6 times higher than for the EMD locomotives. PM-phase PAH emissions for the GE locomotives were three times higher than for the EMD locomotives, and the gas-phase PAH emissions were six to seven times higher. The higher PAH emissions of the GE engines were somewhat surprising, given that GE particulate levels were roughly half to a third those measured for the EMD locomotives.

From the PAH data, no major fuel effect on composite PAH emissions for the three fuels was apparent, even though the fuels differed in aromatic content. Recall that the CARB fuel was a blend of two commercially available "equivalent" fuels, which had an SFC aromatic level of 22.4 mass percent, compared to 30.1 percent for the on-highway fuel, and 29.5 percent for the high sulfur nonroad fuel (see Table 3).

## D. Volatile Organic Fraction of total particulate (VOF)

The soluble organic fraction (SOF) analysis (which was also performed, and the results given in Section G) is more commonly used in PM health-effects assessments. The VOF analysis is important, however, when attempting to quantify the various sources that make up the total PM sampled.

Direct filter injection gas chromatography (DFI/GC) was used to measure the VOF of diesel particulate using the same 90mm Pallflex T60A20 filter collection media used for particulate mass determination. The contribution of unburned lubricating oil to VOF was also determined by an interpretive procedure based on simulated distillation boiling point distribution of a fresh lubricating oil sample. An external standard of locomotive engine lubricating oil was used to quantify the lubricating oil contribution to the VOF. Appendix J contains results from the analysis of selected particulate filters for determination of the VOF.

#### E. Metal Particulate

Metal particulate emissions were measured on two EMD locomotives and two GE locomotives. On one of the triplicate runs on each of the three original test fuels, PM was also sampled using 90mm Nucleopore filter media. These particulate-laden filters were analyzed to determine the weight fraction of metals present in the PM. This information was then used to compute the mass emission rate of metals in the exhaust.

Appendix K gives results from the PM metals analysis. PM metal mass emission rates are expressed in milligrams per hour at each throttle notch. For each element, at each notch, the value reported is either a "ND" for not detected, or the reported mass emission rate. For those reported as ND, there is an accompanying detection level for that element, at that operating condition. The detection limit was based on the detection limit of the ICP-AES instrument and the calibration standards used, and with the mass of PM accumulated on each filter, given the PM sampling conditions. Results reported as "trace" are those which had a elemental concentration above the detection limit, but less than three times the detection limit.

PM metal results in Appendix K show that chromium was the only metal that was measured above detection levels.

#### F. Sulfates

To isolate the specific effect of fuel sulfur content on changes in particulate emissions, sulfate analyses were performed for one of the three runs made on each fuel on each locomotive. Detailed results for individual tests are given in Appendix L, along with the EPA line-haul composite results.

Sulfate collected as particulate is generally composed of sulfuric acid,  $H_2SO_4$ , with associated bound water. The hydration state of the sulfuric acid is very sensitive to the relative humidity in the PM filter weighing chamber. Hence, the chamber humidity is controlled to 50 percent relative humidity to comply with the FTP. At 50 percent relative humidity in the weighing chamber, the hydration of the sulfuric acid results in 1.3 grams of water per gram of  $H_2SO_4$ . This hydration means that the fraction of the total particulate mass due to the sulfate is 2.3 times the mass of the "dry" sulfate alone, because of the associated water. Therefore, it should be noted that sulfate emissions summarized in Table 16 are reported as "wet" sulfate.

Results given in Table 16, and in Figure 12, show that for CARB fuel, which had a sulfur content of 50 ppm, sulfates contributed roughly 2 percent of the total PM from the three EMD locomotives tested, at an average composite level of 8 mg/hp-hr. The average composite wet sulfate emissions from the three GE locomotives using CARB fuel were also 8 mg/hp-hr, but because the total PM emissions for the GE locomotives were considerably lower than for the EMD locomotives, sulfate emissions contributed an average of 7 percent of the total composite PM emissions for the three GE locomotives.

The on-highway fuel had a fuel sulfur level of 330 ppm, but the sulfate emissions for both the EMD and GE locomotives were only slightly higher than were observed while operating on CARB fuel. For the EMD locomotives, the sulfate contributed 3 percent to the average total composite PM, or 10 mg/hp-hr. For the GE locomotives, the average composite wet sulfate emissions were 8 mg/hp-hr, which is the same as with CARB fuel.

The high-sulfur, nonroad fuel had a sulfur level of 4,760 ppm, and the increase in total PM due to sulfate was evident. For the EMD locomotives, wet sulfate contributed 15 percent to the total composite particulate, or 62 mg/hp-hr. For the GE locomotives, wet sulfate contributed 52 percent to the total composite particulate, or 118 mg/hp-hr.

## TABLE 16. SULFATE EMISSIONS SUMMARY

FIGURE 12. SULFATE EMISSIONS SUMMARY

#### G. Soluble Organic Fraction

Selected PM filters were analyzed to determine the SOF of the total particulate using a micro-soxhlet apparatus, in accordance with ARB's "Test Method for Soluble Organic Fraction (SOF) Extraction" dated April 1989. Resulting SOF levels were determined using the filter weight loss method. Essentially, SOF is any material (independent of boiling point) that is soluble in a 70 percent ethanol, 30 percent toluene mixture at specified test conditions. The only variance from the ARB SOF procedure was that the extraction was performed on a 40 percent "pie slice" of the 90 mm PM filter, instead of extracting a whole 47 mm diameter filter. This variance should not adversely affect the SOF results because the mass of material extracted would be similar.

SOF results are given in Appendix M, and EPA line-haul composite results are summarized in Table 17, and in Figure 13. The composite data show that the SOF of total particulate was very high for the EMD locomotives, at about 75 percent of the total PM. The SOF mass emission rate for the EMD locomotives is about four times higher than for the GE locomotives while operating on CARB fuel and the on-highway fuel, and roughly two times as high when using high-sulfur, nonroad fuel. For the GE locomotives, the average composite SOF was about 43 percent of total PM while operating on CARB fuel and the on-highway fuel, but composite SOF increased to 61 percent when operating on high-sulfur, nonroad fuel.

## TABLE 17. SOF EMISSIONS SUMMARY

FIGURE 13. SOF OF PM EMISSIONS SUMMARY

#### V. DDC SERIES 60 DIESEL ENGINE TEST RESULTS

In recent years, many diesel fuel-effects studies have been performed using a Detroit Diesel Corporation (DDC) Series 60 heavy-duty diesel engine. This engine has been used to screen candidate CARB diesel fuel formulations since the late 1980's, and its use is permitted in Title 13 of the California Code of Regulations, Section 2282(g)(4)(A) for certifying a diesel fuel formulation for mobile sources in California. The two batches of fuel from California that were blended to make the CARB fuel used in the locomotive fuel effects project were commercially available CARB-approved equivalent diesel fuel formulations that at one time were qualified in the DDC Series 60 engine.

Given the fact that the CARB fuel used in the locomotive study was a blend of two commercially available CARB fuel formulations, rather than a true CARB reference fuel with an aromatic content of less than 10 percent, the question was raised as to how the CARB fuel blend would compare to the other locomotive test fuels when tested in the DDC Series 60 engine. To answer this question, ARB requested that SwRI run selected locomotive test fuels in the Series 60 engine to assess emissions.

ARB selected three of the four locomotive project test fuels for testing in for the Series 60 engine. The three fuels were CARB fuel, on-highway fuel, and the 0.3 percent sulfur nonroad fuel. Selected properties for all four of the locomotive study test fuels are given in Table 3. Only the 0.476 percent sulfur nonroad fuel used in locomotive testing was not used in the Series 60 tests.

The three locomotive fuels were tested using a 1991 model year 12.7 liter DDC Series 60 engine (SN 06RE001123), with a rated power of 370 hp at a speed of 1,800 rpm, and a peak torque of 1,450 lb-ft at a speed of 1,200 rpm. Transient emission tests were conducted according to the EPA Federal Test Procedure (FTP), as specified in the Code of Federal Regulations (CFR), Title 40, Part 86, Subpart N, "Emission Regulations for New Otto-Cycle and Diesel Heavy-Duty Engines: Gaseous and Particulate Exhaust Test Procedures."

The CARB-equivalent diesel fuel qualification protocols require only transient cycle tests, which are also required for EPA certification of heavy-duty on-highway diesel engines. For this work, four hot-start transient tests on each of the three fuels were run. In addition, ARB requested that selected steady-state tests be run, which could be directly compared to the locomotive test data, which were generated from steady-state tests.

Three steady-state modes were used in the Series 60 tests: rated power to simulate Notch 8 locomotive operation; idle for locomotive Idle, and a condition that represented the Notch 5 engine speed on the GE locomotive, which for the DDC engine was 1,700 rpm, and a load of 540 ft-lb. The three steady-state test modes were then duty-cycle weighted using an "AAR 3-mode" weighting factor developed by SwRI for AAR-funded locomotive testing in the early 1990s. The AAR 3-mode duty cycle weighting factors are 25 percent Notch 8, 25 percent Notch 5, and 50 percent Idle. The AAR 3-mode duty cycle, or AAR-composite, has been shown to give results similar to those obtained for the EPA line-haul duty cycle composite.

Presented in Table 18 are the regulated emission results from four hot-start transient tests on the three locomotive test fuels. Individual transient-cycle test data sheets are given in Attachment N. Table 18 also gives the average results of the four tests, and the difference between the three fuels, expressed as percent change. Comparing CARB fuel to the 0.3 percent sulfur nonroad fuel, CARB fuel resulted in 8.3 percent lower NO<sub>x</sub>, and 23.8 percent lower PM. These test results agree with the NO<sub>x</sub> and PM reductions that ARB attributes to the overall CARB diesel fuel program, which is a 7 percent reduction in NO<sub>x</sub>, and a 25 percent reduction in PM. Comparing the CARB fuel to the Federal on-highway fuel, the CARB fuel had 5.2 percent lower NO<sub>x</sub>, but the PM reduction was only 3.9 percent.

Table 19 gives results from an analysis of the composition of the particulate collected from the transient cycle tests. For each transient-cycle test, particulate was sampled using a pair of 90mm diameter Pallflex T60A20 fluorocarbon-coated glass-fiber filters. Presented below is a discussion of the PM filter analysis results.

A portion of each filter was analyzed to determine the SOF of the total particulate using a micro-soxhlet apparatus, in accordance with ARB's "Test Method for Soluble Organic Fraction (SOF) Extraction" dated April 1989. Resulting SOF levels were determined using the filter weight loss method. Essentially, SOF is any material (independent of boiling point) that is soluble in a 70 percent ethanol, 30 percent toluene mixture at specified test conditions. The only variance from the ARB SOF procedure was that the extraction was performed on a 40 percent "pie slice" of the 90 mm PM filter, instead of extracting a whole 47 mm diameter filter. This variance should not adversely affect the SOF results, because the mass of material extracted would be similar.

Results given in Table 19 show that the SOF of total particulate was essentially the same for CARB fuel and on-highway fuel. For both fuels, about 28 percent of the total PM

was SOF, with a brake-specific SOF of 0.057 g/hp-hr. When using the 0.3 percent sulfur nonroad fuel, the SOF increased to 38.5 percent of the total PM, with a brake specific SOF level almost twice as high as the other two fuels, at 0.102 g/hp-hr.

## TABLE 19. DDC SERIES 60 TRANSIENT FTP PM ANALYSIS

Another portion of each particulate-laden filter was analyzed to determine the VOF of total PM. The analytical technique used to determine the VOF is known as Direct Filter Injection Gas Chromatography (DFI/GC). One significant advantage to the DFI/GC method over other methods (e.g., SOF) is that no solvent extraction procedure is required to obtain a sample for subsequent analyses. DFI/GC is commonly used in diesel engine development because it provides a qualitative assessment of the relative contributions of fuel and unburned lubricating oil to the VOF. The DFI/GC procedure is described in Section II.F of this report.

DFI/GC analysis was used to measure the VOF of the transient test cycle particulate emissions using a portion of the same filter collection media used for SOF determination. Table 19 summarizes the VOF results from the transient tests performed using the three locomotive fuels. As a percentage of total PM, the VOF values for the CARB and on-highway fuels were very similar, at 18 to 19 percent VOF. The average percentage of VOF for the 0.3 percent sulfur, nonroad fuel was 14 percent. The brake-specific VOF for all three fuels was very similar, ranging from about 0.036 to 0.040 g/hp-hr.

The VOF data for the 0.3 percent sulfur nonroad fuel was notably different from the SOF data. Recall that the average SOF level using the 0.3 percent sulfur nonroad fuel was roughly twice as high as for the other two fuels, 0.057 verses 0.102 g/hp-hr. The 0.102 g/hp-hr SOF level for the 0.3 percent sulfur nonroad fuel is nearly three times higher than the average VOF result of 0.036 g/hp-hr. This difference suggests that the sulfate and other sulfur-containing compounds, and associated water, may have been physically removed from the filter during the SOF extraction process, and inadvertently included as SOF. This observation raises concern over the possibility of double-counting sulfate compounds in PM filter analysis, where sulfur compounds are counted once as sulfate, and potentially again as part of the SOF. This double-counting could lead to erroneously low estimates of the carbon soot fraction of PM. These errors would be proportional to the sulfur content of the fuel, with higher sulfur fuels having the largest potential for error.

To isolate the specific effect of fuel sulfur content on change in particulate emissions, sulfate analyses were performed. Sulfate emissions from the transient test cycles run on the DDC Series 60 engine are summarized in Table 19. Sulfate is reported as "wet" sulfate, because sulfate particulate is generally composed of sulfuric acid,  $H_2SO_4$ , with associated bound water. At 50 percent relative humidity used in the weighing chamber, the hydration of the sulfuric acid results in 1.3 grams of water per gram of  $H_2SO_4$ . This hydration means that the fraction of the total particulate mass due to the sulfate is 2.3 times the mass of the "dry" sulfate alone, because of the associated water.

in Table 19 show that for CARB fuel, which had a sulfur content of 50 ppm, sulfates contributed only 0.9 percent of the total PM, or 1.9 mg/hp-hr. The on-highway fuel had a fuel sulfur level of 330 ppm, and the sulfate contributed an average of 3.3 percent of the total PM, or 7.0 mg/hp-hr. The nonroad fuel had a sulfur level of 3,190 ppm, and sulfate contributed an average 24.9 percent of the total particulate, or 65.8 mg/hp-hr.

Table 19 also gives an estimate of the amount of carbon soot in the PM. Carbon soot was estimated by subtracting the VOF and the "wet" sulfate portions from the total PM. The remainder was considered to be carbon soot. Inspection of the data in Table 19 shows that the estimated mass of carbon soot in total PM is essentially the same for all three fuels. Recall that the VOF was also essentially the same for all three fuels, leaving variation in sulfates as the principal cause for changes in PM emissions among the three fuels tested.

Steady-state test results are given in Table 20 in the form of 3-mode AAR-composite values. Detailed test data for the individual steady-state tests on the DDC Series 60 engine are given in Appendix N. The original test plan called for duplicate 3-mode tests using each fuel. However, due to variability in NO<sub>x</sub> and PM results during tests with CARB fuel, three additional tests were run using CARB fuel. All the test results are included in Table 20.

Table 20 also gives the average AAR-composite results, and the difference between emissions for the three fuels, expressed as percent change. Comparing CARB fuel to the 0.3 percent sulfur nonroad fuel, CARB fuel resulted in 5.1 percent lower  $NO_x$ , and 37.3 percent lower PM.

Presented in Table 21 is a summary of both transient and steady-state emission results from the DDC Series 60 engine, along with the average change in emissions observed for the three GE locomotives and the three EMD locomotive engines. Note that no tests were run on the EMD locomotives using the 0.3 percent sulfur nonroad fuel, but data for the EMD engines operating on the 0.476 percent sulfur fuel is included for comparison purposes

The data in Table 21 show that during steady-state operation, the NO<sub>x</sub> response of the DDC engine was very similar to that observed for both the GE and EMD locomotives. However, during transient operation, the NO<sub>x</sub> response of the DDC engine was stronger than observed during steady-state tests.

<ul> <li>Notes: a - Average of the three GE locomotives tested, using the EPA line-haul duty cycle.</li> <li>b - Average of the three EMD locomotives tested, using the EPA line-haul duty cycle.</li> <li>c - The EMD locomotives were not tested with the 0.3 percent sulfur fuel. Data shown is for tests run using the 0.476 percent sulfur nonroad fuel.</li> </ul>													

Transient PM emission response for the DDC engine was generally similar to that observed for the GE locomotive. The fuel effect on PM emissions for the two-stroke EMD locomotives was roughly half that observed on GE locomotives. This difference is due to the relatively high PM emission level of the EMD locomotives, compared to that of the GE locomotives and the DDC Series 60 engine. A significant portion of the EMD PM is VOF attributable to lubricating oil consumption, and as such, a large portion of the PM is unaffected by fuel type. Therefore, the observed change in PM emissions as a function of fuel type is smaller.

#### VI. SUMMARY

This report documents results from test work intended to assess changes in locomotive exhaust emissions with changes in the type of diesel fuel used. In this project, three commercially available fuels were tested in a total of six 4,000 to 4,400 hp line-haul locomotives; three manufactured by the Electro-Motive Division of General Motors Corporation (EMD), and three manufactured by the Transportation Systems Division of the General Electric Company (GE). The commercially available fuels included a CARB fuel, a Federal on-highway fuel, and high-sulfur, nonroad fuel. Due to the fact that the sulfur level of the "high- sulfur" fuel was higher than nonroad diesel fuel typically purchased by the railroads, a fourth fuel was also used in the three GE locomotives, which was a nonroad fuel with a sulfur level of 3,190 ppm (0.32 percent). In this report, this fourth fuel is referred to as the "0.3 percent sulfur" fuel, and is considered to be more representative of high sulfur nonroad diesel fuels used by the railroads. Test results from the program were provided to ARB and the AAR for detailed analysis.

Focusing on the major changes in EPA line-haul composite emissions that occurred with the different fuels, Table 22 summarizes the percent changes in regulated exhaust emissions that occurred when switching fuels. Compared to the high-sulfur, nonroad diesel fuel, average composite  $NO_x$  emissions were 6-7 percent lower with CARB fuel, which corresponds to about 0.8 g/hp-hr. This level of  $NO_x$  reduction is similar to the reduction observed for on-highway diesel engines.

Figure 14 shows the effect of test fuel sulfur content on the composite PM emissions from the two models of locomotives tested. The PM reduction with CARB fuel was largely attributable to the reduced sulfur content of the fuel, and on a g/hp-hr basis, the response to PM was essentially the same for each locomotive model. Sulfate analysis performed on the PM samples quantified the contribution of sulfate to total PM emissions.

Changes to composite HC and CO emissions with CARB fuel and the high-sulfur nonroad fuel were mixed, and did not show any strong trends. There was little change in smoke, as well. However, it is anticipated that ARB and AAR statistical analyses of the data will determine what changes in emissions are statistically significant.

Detailed test results for selected unregulated emissions, including benzene, 1,3butadiene, formaldehyde, acetaldehyde, acrolein, gas-phase and PM-phase PAH compounds, the volatile organic fraction of total particulate, PM metals, sulfates, and the soluble organic fraction, are included in this report. Notable changes in sulfate and SOF were observed between the test fuels, with the CARB fuel demonstrating considerable reductions in both sulfate and SOF. No statistical analyses of data was performed as part of this program.

TABLE 22.	AVERAGE CHANGE IN REGULATED LOCOMOTIVE EXHAUST
	EMISSIONS BETWEEN TEST FUELS

When the locomotive test fuels were evaluated in a DDC Series 60 diesel engine, which was the engine used to qualify equivalent CARB fuel formulations, results showed that during steady-state operation, the  $NO_x$  response of the DDC engine to the locomotive test fuels was very similar to that observed on the GE and EMD locomotives. During transient operation, the  $NO_x$  response of the DDC engine was consistently stronger than observed during steady-state tests. PM response of the DDC engine as a function of fuel type was generally similar to that observed for the GE locomotive.

FIGURE 13. EFFECT OF TEST FUEL SULFUR CONTENT ON PM EMISSIONS

Appendix O to this report documents results from exhaust particulate size distribution measurements performed on one of the three GE locomotives tested, UP No. 9724. For the particulate size determination work reported in Appendix O, two fuels were compared; CARB diesel and a nonroad diesel fuel with a fuel sulfur level of 0.3 percent (3,190 ppm). Tests were run at only two operating conditions: Idle and Notch 8 (rated power). Particle size distribution was measured using a Model 110 micro-orifice uniform deposit impactor (MOUDI). Additional analysis of the size-segregated particulate included determination of the volatile organic fraction (VOF), elemental analysis, and anion and cation analyses.

#### FOREWORD

This project was performed for the California Air Resources Board (ARB) under SwRI Project 08-02062-003. The technical representative for ARB was Mr. Tony Brasil, Stationary Source Division - Fuels Section. The Principal Investigator was Mr. E. Robert Fanick, Senior Research Scientist, and the Project Manager for this work was Mr. Steven G. Fritz, Senior Research Engineer, both in the Department of Emissions Research. Mr. Michael J. Dammann, Group Leader in the Chemistry and Chemical Engineering Division, was responsible for the elemental analyses. SwRI technical personnel involved in engine operation, emissions sampling, and emissions analysis included Messrs. C. Eddie Grinstead, William L. Shackelford, and Ernesto San Miguel, all in the Department of Emissions Research. Ms. Yolanda Rodriguez and Ms. Kelley L. Strate performed the chemical analysis. Data reduction was performed by Ms. Kathleen M. Jack, Ms. Deborah A. Liston, and Ms. Sylvia G. Nino, also all in the Department of Emissions Research.

#### **EXECUTIVE SUMMARY**

This report documents results from exhaust particulate size distribution measurements performed on a 4,400 hp General Electric model DASH9-44CW diesel locomotive engine. This locomotive (UP No. 9724) was one of six locomotives tested for the California Air Resources Board (ARB) as part of a fuel effects study.

For the particulate size determination work reported herein, two fuels were compared; CARB diesel and a nonroad diesel fuel with a fuel sulfur level of 0.3 percent (3,190 ppm). These fuels were two of the four fuels used in the ARB locomotive fuel effects study. Tests were run at only two operating conditions: Idle and Notch 8 (rated power). Particle size distribution was measured using a Model 110 micro-orifice uniform deposit impactor (MOUDI). Additional analysis of the size-segregated particulate included determination of the volatile organic fraction (VOF), elemental analysis, and anion and cation analyses.

Less than one percent of the particulate for both fuels was larger than 2.5 Fm ( $PM_{2.5}$ ), at both Idle and Notch 8. As expected, the total particulate mass rate was higher with the 0.3 percent sulfur nonroad diesel fuel at both operating conditions. One significant finding of this study was that the PM mass emission rates were similar for both fuels down to a particle size of 0.17 Fm. Most of the difference in total PM observed between the two fuels occurred in the smaller size ranges, 0.17 Fm to 0.09 Fm, 0.09 Fm to 0.056 Fm, and less than 0.056 Fm, where the 0.3 percent sulfur fuel had significantly higher mass emission rates. Subsequent analysis of the PM samples showed that the increased PM at the smaller size fractions was largely attributed to fuel-derived portion of the VOF and to sulfate emissions. Another interesting finding from this study was that for both fuels, the particle size distribution at Idle was monomodal, and at Notch 8 it was bimodal.

An elemental analysis was performed on selected size ranges, and only five elements detectable by XRF were present in enough quantity to be above detection limits. These elements were barium, manganese, nickel, sulfur, and zinc. The various metal elements were mostly attributed to engine wear metals, and the sulfur came from the fuel and lubricating oil. Except for sulfur, the metal elements contributed only a small fraction to the total particulate mass. At both Idle and Notch 8, most elements detected were in the 0.54 Fm to 0.31 Fm, 0.31 Fm to 0.17 Fm, and 0.17 Fm to 0.09 Fm particle size ranges.

For the anions and cations analyzed, sulfate was detected at the highest mass emission rates, especially with the higher sulfur fuel. Chloride, nitrate, and potassium ions were detected, but contributed only a small fraction to the total particulate mass.

### I. INTRODUCTION AND BACKGROUND

This project was an experimental program intended to characterize the size distribution of exhaust particles from a locomotive engine. Particulate characterization by particle size included the volatile organic carbon content, elemental analysis, and anion and cation mass emission rates. The work was performed to determine the particulate composition and how the particulate characteristics change in relation to the size of particle. Exhaust emission and fuel consumption measurements were performed using a 4,400 hp, General Electric (GE), model DASH9-44CW locomotive, provide by Union Pacific Railroad (UP).

The EPA definition of an engine exhaust particulate is any material collected on a fluorocarbon-coated glass fiber or fluorocarbon-based (membrane) filter, from a dilute exhaust stream, at a sample zone temperature less than 52EC (125EF). For particulate measurement, the engine's raw exhaust is typically diluted in a tunnel, which is generally about 8 to 18 inches in diameter and about 20 feet long. The dilution ratio generally ranges from 2:1 to 20:1, depending on engine operating conditions, tunnel air flow capacity, and system control characteristics required to meet the sample zone temperature requirements. For a given engine, the number and size of particles in the exhaust are functions of many variables including the sample probe location in the plume. The predominant size range in terms of total mass is larger than 0.1 micron, and in terms of number of particles, the predominant size is below 0.1 micron. The dependence of particle size and number on sample probe location is directly related to the temperature, dilution, and "age" of the particles. As engine exhaust cools, the higher molecular weight gaseous hydrocarbons begin to condense into aerosols, the particles tend to agglomerate, and adsorption of hydrocarbons may occur. Each mechanism results in larger and heavier particles.

In this study, the aerodynamic diameter is defined as the diameter of a unit density sphere (1 g/cc) having the same settling speed in air as the measured particle. Sizing devices such as cascade impactors use aerodynamic principles to size particles. In an impactor, a sample containing particles with a mixture of shapes and densities is fractionated and collected according to aerodynamic characteristics. As the sample stream passes through stages in the impactor with apertures of decreasing width or diameter, flow is accelerated and progressively smaller particles collect on impaction plates. Particles which are aerodynamically equivalent in size to the unit density spheres are collected on specific stages, calibrated under similar conditions. The mass collected on each stage indicates the percentage of particles within a specific aerodynamic diameter range.

## **II. TECHNICAL APPROACH**

Testing was performed at the Southwest Research Institute (SwRI) Locomotive Exhaust Emissions Test Center in San Antonio, Texas. This unique facility was established in 1993 in cooperation with the Association of American Railroads (AAR), and is the only non-original equipment manufacturer (non-OEM) facility capable of performing locomotive exhaust emission tests.

Presented below is an overview of the technical approach used to conduct locomotive exhaust emissions testing for this study. A description of the locomotive selected for testing, engine power measurement, fuel consumption measurement, the test fuels used in this program, exhaust emissions test procedures, and particulate measurement procedures are also included. Analytical procedures for particulate characterization are included in Section III of this report.

# A. <u>Test Locomotive</u>

Exhaust particulate size distribution measurements were performed on a General Electric (GE) model DASH9-44CW diesel locomotive engine. This locomotive, UP No. 9724, was one of six locomotives tested for the California Air Resources Board (ARB) as part of a fuel effects study. UP No. 9724 was manufactured in July 1994, and has the serial number 47870. It was equipped with a 4,400 hp, GE model 7FDL16N62, turbocharged diesel engine (SN 970815R), which was remanufactured by GE in August 1997.

### B. Engine Power Measurement

Most line-haul locomotives are equipped with the "dynamic brake" feature in which the electric motors used for traction are reverse-excited to become generators to slow the train. The electrical power generated is dissipated in resistance grids. Those locomotives with the self-load feature can dissipate the main alternator power into these "dynamic brake" resistance grids. UP. No. 9724 was equipped with resistance load grids that were capable of loading the engine to its full power level of 4,400 hp.

The goal of power measurements was to compute the net engine power produced to perform work, referred to as flywheel or "gross" power. Gross power for the GE locomotive was recorded from the on-board computer display. Gross power represents the sum of "traction power" plus "auxiliary power."

# C. <u>Fuel Consumption Measurement</u>

Diesel fuel consumption rate was measured on a mass basis, using a mass flow meter adapted from laboratory use at SwRI. The system was equipped with a heat exchanger to control fuel supply temperature to  $90\pm10^{\circ}$ F. Hot return fuel from the engine that normally returns to the locomotive fuel tank was cooled before returning to the fuel measurement reservoir ("day" tank) to assure consistent fuel supply temperature to the engine.

# D. <u>Test Fuels</u>

Two fuels were used for this particulate characterization study. The first fuel was a 0.3 percent sulfur nonroad diesel fuel, with an aromatic level of about 40 percent and a cetane number of 44.5. The second fuel was a blend of two commercially available CARB diesel fuels with a sulfur level of 50 ppm (0.005 percent) and an aromatic content of 22 percent by volume. This fuel consisted of 8,000 gallons of commercially available CARB-approved diesel fuel from the Texaco refinery in Los Angeles, California plus another 8,000 gallons of commercially-available CARB-approved diesel fuel from the ARCO refinery in South Gate, California. Each fuel was delivered to the SwRI Locomotive Exhaust Emissions Test Center by truck and the fuels were mixed in a single railroad tank car. Table 1 gives selected properties for the two fuels. Table 2 gives the results of a metals analysis of the two fuels.

# E. <u>Regulated Exhaust Emissions Test Procedure</u>

SwRI used the Federal Test Procedure (FTP) for locomotives as detailed in 40 CFR Part 92, Subpart B as the basis for emission measurement techniques. For this study, two throttle notch settings were used: Idle and Notch 8.

Particulate emissions were measured at each test point using a "split then dilute" technique, in which a portion of the raw locomotive exhaust was "split" off of the total flow and mixed with filtered air in a 10-inch diameter dilution tunnel. The split sample was transferred to the dilution tunnel through a 2-inch diameter stainless steel tube that was insulated and electrically heated to 375°F. This dilution tunnel was located at ground level, next to the locomotive, as shown in Figure 1. Particulate samples from the dilute exhaust were collected using an isokinetic sampling probe shown in Figure 2.

Before emission testing was started, the engine was first brought to operating temperature. This procedure involved operating the locomotive at Notch 8 for at least 15 minutes. After the warm-up period, testing began with Idle using the 0.3 percent sulfur fuel. Four consecutive repeat tests were performed to collect sufficient samples for the various analytical procedures. The engine was then brought to Notch 8, and the sequence of four consecutive tests was repeated. After a fuel change to the CARB diesel, the sampling sequence was repeated at Idle and Notch 8.

# **III. DESCRIPTION OF ANALYTICAL METHODS**

This section of the report describes the analytical methods used for assessing particle size distribution of particulate emissions, and the subsequent chemical characterization of the particulate collected.

# A. MOUDI for Particle Size Distribution

Particle size distribution was measured using a Model 110 micro-orifice uniform deposit impactor (MOUDI) with an isokinetic sampling probe located within the dilution tunnel. The sample flow rate through the MOUDI was 30 L/min. Nine MOUDI stages were used to collect particulate having particle diameter cut-off of ranges of greater than 6.2 Fm, 3.1 to 6.2 Fm, 1.8 to 3.1 Fm, 1.0 to 1.8 Fm, 0.54 to 1.0 Fm, 0.31 to 0.54 Fm, 0.17 to 0.31 Fm, 0.09 to 0.17 Fm, and 0.056 to 0.09 Fm. The last stage was followed by a 47 mm Pallflex T60A20 backup filter to collect particles below 0.056 Fm. Figure 3 shows the MOUDI installed at the locomotive test center.

FIGURE 3. MOUDI PARTICLE SIZE SYSTEM USED AT LOCOMOTIVE TEST CENTER

The MOUDI operating principal is the same as any inertial cascade impactor with multiple nozzles. At each stage, jets of particle-laden dilute exhaust impinge upon an impaction plate. Particles larger than the mean diameter cut-size of that stage have inertia sufficient to cross the air streamlines to impact the plate. Upon contact with the plate, the particles remain on the impaction plate. Smaller particles have less inertia, cannot cross the streamlines, and proceed to the next stage. Smaller nozzles, with higher air velocity, are used to separate finer particles. The process continues through the cascade impactor until particles smaller than the last stage collection capability are collected on the final glass fiber backup filter. By rotating every other stage of the impactor and holding the others stationary, every nozzle plate rotates relative to its impaction plate. This relative rotation allows the MOUDI to achieve near uniform particle deposition on the impaction plates. Figure 4 shows particulate collected on one of the impaction plates of a MOUDI stage.

# FIGURE 4. PARTICULATE COLLECTED ON ONE OF THE IMPACTION PLATES OF A MOUDI STAGE

For gravimetric particle size distribution and for the volatile organic fraction (VOF) determinations, uncoated aluminum foil plates were used to collect samples. These foils are the typical collection media used for the MOUDI system. Nucleopore substrates were used in place of the aluminum foil plates to collect samples for subsequent characterization of metals, cations, and anions. In all, four runs at each operating condition were performed. Run 1 used standard uncoated 47-mm aluminum foil plates to accumulate particulate. These filters were used for gravimetric mass determination. Run 2 also used uncoated 47-mm aluminum foil

plates. These plates were used to replicate data for gravimetric mass determination, and were then used to determine the volatile organic fraction (VOF) of the collected particulate. Run 3 used 47-mm Nucleopore filter media as plates, in place of the conventional aluminum foils. These filters were used for subsequent elemental analysis, as described below in Section III.C. Run 4 used a second set of 47-mm Nucleopore filter media. These filters were used for subsequent analysis for anions and cations, as described below in Section III.D.

# B. <u>DFI/GC for VOF</u>

Direct filter injection gas chromatography (DFI/GC) was used to determine the VOF of the particulate at selected size fractions. VOF is defined in this study as organic material that responds on a flame ionization detector (FID), and has a boiling point of less than approximately 600EF. In addition, the contribution of unburned lubricating oil to VOF was also determined by an interpretive procedure based on simulated distillation boiling point distribution of a lubricating oil sample from the locomotive. The difference between the unburned oil derived VOF and the total VOF is a combination of unburned fuel, oxidized lubricating oil, and oxidized fuel components with a lower boiling temperature than the lubricating oil. For this study, the combination of these lower boiling components will be defined as "fuel-derived VOF".

Direct DFI/GC processing of the aluminum foil plates was not possible, so the material collected on each foil was transferred to 47-mm Pallflex T60A20 particulate filters for analysis. Lubricating oil from the locomotive was used to quantify the boiling point distribution of unburned lubricating oil contribution to the VOF.

VOF analyses were conducted using a Perkin Elmer Model 8500 gas chromatograph (GC) equipped with a uniquely designed filter injection system and a FID. Pallflex filters containing the samples transferred from the foils were placed into the injector, which was subsequently inserted into a cool zone of the DFI/GC to allow any oxygen in the system to be purged without losing any sample by desorption. When all oxygen had been purged from the system, the injector was pushed into a hot zone of the GC, where the volatile materials were desorbed and deposited into a cool column. A GC temperature program was then used to separate the volatilized compounds by boiling point. These compounds were then detected with a FID.

### C. ICP/MS for Elemental Analysis

An inductively coupled plasma, mass spectroscopy (ICP/MS) method was used for determining the elemental content of particulate collected on selected MOUDI plates. Nucleopore filters or plates from individual stages were digested in a mixture of nitric and perchloric acid, followed by digestion with aqua regia. The resulting solution was analyzed by ICP/MS for the elements given in Table 3.

Aluminum - Al	Antimony - Sb	Arsenic - As

TABLE 3. ELEMENTS STUDIES BY ICP/MS

The ICP/MS instrument was standardized using reference materials that were traceable to the National Institute of Standards and Technology (NIST). Prior to the analysis of any samples, the standardization was also verified with a second NIST traceable reference material. This second standard was from a different lot or manufacturer than the standardization material, and served as a check sample. Immediately after a check sample was run, a blank sample was also run to verify the zero setting of the standardization. The check sample was required to be within the control limits of 90-110 percent recovery of the certified value. The absolute value of the check blank was required to be below the reporting limit for the samples. If either condition was not met, the analysis was terminated and the instrument re-standardized and re-checked. The check sample and check blank were re-run after every ten samples and at the end of the run to ensure that the instrument remained in control throughout the entire run of ten samples. The same control limits were used for the continuing check samples. If a continuing check sample fell out of the control limits, the analysis was terminated, the instrument re-standardized, and all samples processed since the

last compliant check sample were re-run. Detection limits were on the order of 1 to 5 Fg/filter for most elements.

# D. <u>IC for Anions and Cations</u>

Anions and cations accumulated on each Nucleopore filter impactor plate were quantified using an ion chromotography (IC) process, where selected stages were extracted by shaking each Nucleopore filter in a solution of 60 percent isopropanol (IPA) and 40 percent water. Analyses of the extracted anions and cations were conducted using an IC equipped with a conductivity detector.

# 1. Anions -- Sulfate, Nitrate, and Chloride Ions

Sulfuric acid on the filter was converted to ammonium sulfate by exposure to ammonia vapor in a conditioning chamber. The soluble sulfates and other anions were then leached from the filter with a measured volume of 60 percent IPA and 40 percent water. An aliquot of this extract was injected via autosampler into an IC. Anions were separated by analytical column with a dilute solution of sodium bicarbonate and sodium carbonate as the eluent, and then passed through a conductivity detector. The retention time on column provide identification of the anions, with the intensity of the signal corresponding to the concentration of the anion detected.

# 2. Cations -- Ammonium and Potassium Ions

Cations were analyzed in a similar manner as the anions except the eluent was nitric acid. The soluble cations were leached from the Nucleopore filter with a measured volume of 60 percent IPA and 40 percent water. An aliquot of this extract was injected via autosampler into an IC. Cations were separated by analytical column, and passed through a conductivity detector. The retention time on column provided identification of the cations, with intensity of the signal corresponding to the cation concentration.

#### **IV. TEST RESULTS**

#### A. <u>Particle Size Distribution</u>

Table 4 summarizes the results of the GE locomotive particle size distribution at Idle and Notch 8 for both fuels. Given are particulate matter (PM) mass emission rates in ten discrete particle size ranges, and a total particulate mass rate, which is the sum of all the stage fractions collected plus the backup filter.

As described in Section III.A of this report, duplicate tests were performed using the standard foil media and Nucleopore media in the MOUDI at each of the two operating conditions, and for each of the two test fuels. The data in Table 4 shows that the particle size distribution obtained with the foil plates and the Nucleopore media as an impaction plate yielded similar results, although the sum of the stage values (the total PM emission rate) was consistently higher when using the Nucleopore media compared to the foil plates. Table 4 also contains the PM rate for each test condition and fuel that is based on conventional PM sampling techniques using 90mm Pallflex T60A20 filter media. The value reported as "Total PM by 90mm" is the average of triplicate tests reported to the ARB as part of the main test program on this locomotive. Comparing the 90mm PM results to the PM totals by the MOUDI show that the Nucleopore media seemed to agree better than the foils, with the possible exception of the first Notch 8 run with the 0.3 percent sulfur fuel, where the total PM by MOUDI was almost twice as high as the 90 mm PM. Comparing the PM totals by MOUDI using foil plates are often compared against total PM measured with conventional sampling systems, and MOUDI total PM values are typically in the range of 60 to 90 percent of those measured by conventional 90mm filters. In this case, the Nucleopore filters used as impaction plates seemed to collect more mass at each stage compared to the foil plates, although the size distributions were similar. Due to the fact that the foil plates are the collection media typically used in MOUDI sampling, the following discussion of particle size is based on data using the foils.

The duplicate runs using the foil media were averaged, and the results are presented in Figure 5, in percentages of total PM mass as a function of particle size. At Idle, for both fuels, about 1 percent of the total PM mass was from particles larger than 2.5 Fm. At Notch 8, less than 1 percent of the total PM mass was from particles larger than 2.5 Fm, for both fuels. Figure 5 also shows that the 0.3 percent sulfur fuel had a larger percentage of smaller particles than the CARB diesel, at both Idle and Notch 8. Also, there was a larger fraction of smaller particles at Notch 8 than at Idle.

Figure 6 shows the particulate mass emission rate during Idle operation as a function of particle size, based on the aluminum foil collection plates. Both fuels exhibited a monomodal distribution, with the largest mass fraction at the 0.31 to 0.54 Fm size range. The PM mass emission rate was higher with the 0.3 percent sulfur fuel at all size ranges except at the 0.17 to 0.31Fm size range.

## TABLE 4. GE LOCOMOTIVE ENGINE PARTICULATE EMISSION SIZE DISTRIBUTION SUMMARY

Figure 7 shows the particulate mass emission rate during Notch 8 operation as a function of particle size, based on the aluminum foil collection plates. Comparing Idle to Notch 8, there is a noticeable shift in the particle size distribution toward smaller particles, and the total mass emission rate is about an order of magnitude higher. At Notch 8, less than 3 percent of the particulate mass emission was above 0.54 Fm for both fuels. An interesting characteristic of the size distribution at Notch 8 is that it was bimodal for both fuels, with one peak at 0.31 to 0.54 Fm size range, like that observed at Idle, but with a second peak around the 0.09 to 0.17Fm size range. It is at this peak in the smaller particle size range where the greatest difference in PM emissions between the two fuels was observed, with PM mass emissions with the 0.3 percent sulfur fuel nearly twice as high as the CARB diesel in the three size ranges below 0.17 Fm.

FIGURE 6. PARTICLE SIZE DISTRIBUTION AT IDLE

FIGURE 7. PARTICLE SIZE DISTRIBUTION AT NOTCH 8

#### B. Volatile Organic Fraction (VOF) of Particulate

Stages with mean diameter ranges of 0.54 Fm to 0.31 Fm, 0.31 Fm to 0.17 Fm, and 0.17 Fm to 0.09 Fm for Idle were analyzed by DFI/GC for VOF. At Notch 8, the same three stages used in Idle VOF analysis, plus the 0.09 Fm to 0.056 Fm stage, and the less than 0.056 Fm backup filter were examined. Particulate mass loadings for the other stages were too small to permit particulate characterization by VOF. The DFI/GC procedure provides a result based on the percentage of total PM that is VOF. In this case, the percentage of the PM was measured using the MOUDI foil plates. The percent VOF determined for each stage was applied to the average PM emission of the two runs made with the foil plates at each test condition. The VOF results are presented in Table 5, and in Figures 8 and 9.

Engine Condition	Fuel	Average Total Particulate, g/hr	Size Range, Fm	% VOF	VOF, g/hr	% Unburned Oil of VOF	Unburned Oil, g/hr	Fuel-Derived VOF, g/hr

	045	070	0.31-0.17	9.1	22.0	21	4.6	17.4
	CAR B	270	0.17-0.09	7.4	17.9	25	4.5	13.4
	Diese I		0.09-0.056	6.0	14.5	12	1.7	12.8
			<0.056	8.2	20.1	42	8.4	11.7

TABLE 5. VOLATILE ORGANIC FRACTION (VOF) OF PARTICULATE

The data given in Table 5 shows that the VOF of the PM emissions from the GE engine is relatively low, and makes up only 5 to 10 percent of the total PM mass. Figures 8 and 9 show that the VOF is largely fuel-derived, at both Idle and Notch 8. The mass rate of unburned lubricating oil-derived VOF was generally similar for both fuels, especially during Notch 8 operation. At Idle, the lubricating oil derived VOF was higher with the 0.3 percent sulfur diesel fuel, compared to the CARB diesel, with notable increases observed at the two larger size ranges analyzed. At Notch 8, the largest contribution to the VOF from unburned lubricating oil was at the smallest size range analyzed, which was less than 0.056 Fm.

#### C. <u>Elemental Analysis</u>

MOUDI stages using Nucleopore filters and with particle sizes of 0.54 Fm to 0.31 Fm, 0.31 Fm to 0.17 Fm, and 0.17 Fm to 0.09 Fm for Idle were analyzed by ICP/MS for selected elements. At Notch 8, the same stages, plus the 0.09 Fm to 0.056 Fm stage, and the less than 0.056 Fm backup filter were examined. Particulate mass loadings for the other stages were too low to permit particle characterization. A total of 44 elements were analyzed for, but most were below their detection limit.

Appendix A gives the tabulated results of the elemental analysis on selected MOUDI stages. Only four elements (barium, magnesium, potassium, and sulfur) were above the detection limit for the stages analyzed, and only sulfur was found repeatedly. Several elements were found at trace levels, defined as being present above the detection limit, but at a concentration less than three times the detection limit.

### D. Anion and Cation Emissions

MOUDI stages with size ranges of 0.54 Fm to 0.31 Fm, 0.31 Fm to 0.17 Fm, and 0.17 Fm to 0.09 Fm for Idle were analyzed by IC for anion and cation emissions. At Notch 8, the same three stages, plus the 0.09 Fm to 0.056 Fm range were examined. Particulate mass loadings for the other stages were too small to permit analysis. The anions included chloride, nitrate, and sulfate ions; and the cations included ammonium and potassium ions. Analyses for bromine were also conducted, but no bromine was found in any of the samples. Table 6 presents the results for the anions and cations by particle size distribution.

Engine Condition	Fuel	Particle Size Range, Fm	Chloride Ion, mg/hr	Nitrate Ion, mg/hr	Dry Sulfate Ion, mg/hr	Ammonium Ion, mg/hr	Potassium Ion, mg/hr
		0.54 - 0.31	1.8	6.8	70	91	34

## TABLE 6. EXHAUST ANION AND CATION MASS EMISSIONS

## 1. Chloride Ion Mass Emission Rates

Figures 10 and 11 show the chloride ion mass emission rates by particle size distribution for the two engine conditions. The chloride ion mass emission rates using CARB fuel were higher than for the 0.3 percent sulfur nonroad diesel fuel at both Idle and Notch 8.

Chloride ion mass emission rates at Notch 8 were the lowest for the 0.31 Fm to 0.17 Fm particle size range. At the 0.09 Fm to 0.056 Fm range with the 0.3 percent sulfur fuel, no chloride ion was detected. The chloride ion mass emissions were also greater for all size ranges with the CARB fuel, except for the 0.17 Fm to 0.09 Fm range at Notch 8.

FIGURE 10. CHLORIDE ION MASS EMISSION RATE AT IDLE

FIGURE 11. CHLORIDE ION MASS EMISSION RATE AT NOTCH 8

## 2. Nitrate Ion Mass Emission Rates

Figures 12 and 13 show the various nitrate ion mass emission rates by particle size distribution for the two engine conditions. Nitrate ion mass emission rates at Notch 8 were at least one order of magnitude greater than at Idle for both fuels. The differences in nitrate ion mass emission rates between the two fuels for all size ranges did not appear to be related to the nitrogen content in the fuel.

FIGURE 12. NITRATE ION MASS EMISSION RATE AT IDLE

FIGURE 13. NITRATE ION MASS EMISSION RATE AT NOTCH 8

#### 3. Sulfate Ion Mass Emission Rates

To isolate the specific effect of fuel sulfur content on change in particulate emissions, sulfate analyses were performed. Sulfate emissions are summarized in Table 7. Sulfate is reported here as "wet" sulfate, because sulfate is generally composed of sulfuric acid,  $H_2SO_4$ , with associated bound water. The hydration state of the sulfuric acid is very sensitive to the relative humidity in the PM filter weighing chamber. At 50 percent relative humidity in the weighing chamber, the hydration of one gram of sulfuric acid results in 1.3 grams of water per gram of  $H_2SO_4$ . This hydration means that the fraction of the total particulate mass due to the sulfate is 2.3 times the mass of the "dry" sulfate alone, because of the associated water.

Results given in Table 7 show that at Idle, sulfates contribute only a small percentage of the total PM, independent of the fuel. At Notch 8, however, sulfate made up over half of the total PM at the size range 0.09 to 0.056 Fm while using the 0.3 percent sulfur nonroad diesel fuel. For CARB diesel, which had a sulfur content of 50 ppm, sulfates contributed only 14 percent of the total PM at the same size range.

Engine Condition	Fuel	Particle Size Range, Fm	Total <sup>a</sup> PM, mg/hr	"Dry" Sulfate, mg/hr	"Wet" Sulfate <sup>ь</sup> , mg/hr	"Wet" Sulfate, % of total PM	
	0.001	0.54 - 0.31	12,000	70	160	1	
	0.3% Sulfur	0.31 - 0.17	14,000	110	260	2	
Idle		0.17 - 0.09	10,000	120	280	3

TABLE 7. SULFATE MASS EMISSION SUMMARY

Figures 14 and 15 show the sulfate mass emission rates by particle size distribution for the two engine conditions. The sulfate ion mass emission rates at Idle increased with decreasing particle size for the 0.3 percent sulfur fuel, and decreased with decreasing particle size with the CARB diesel.

Sulfate ion mass emission rates at Notch 8 increased with decreasing particle size for both fuels. The mass emission rates for sulfate ion with the 0.3 percent sulfur fuel were almost a factor of five times greater than with the CARB diesel.

FIGURE 14. DRY SULFATE ION MASS EMISSION RATE AT IDLE

## 4. Ammonium Emissions

Figures 16 and 17 show ammonium ion mass emission rates by particle size distribution for the two engine conditions. Ammonium mass emission rates at Idle increased with smaller particle size for the 0.3 percent sulfur fuel, and decreased with smaller particle size range with the CARB diesel. Overall, ammonium mass emissions were greater for the 0.3 percent sulfur fuel, except for the 0.54 to 0.31 Fm size range for CARB diesel. Ammonium ion mass emissions at Notch 8 increased with decreasing particle size for both fuels.

FIGURE 16. AMMONIUM ION MASS EMISSION RATE AT IDLE

FIGURE 17. AMMONIUM ION MASS EMISSION RATE AT NOTCH 8

#### 5. Potassium Ion Mass Emission Rates

Figures 18 and 19 show potassium ion mass emission rates by particle size distribution for the two engine conditions. No trends were noted in the potassium ion mass emission rates for any particle size range with either fuel or engine operating condition.

FIGURE 18. POTASSIUM ION MASS EMISSION RATE AT IDLE

## FIGURE 19. POTASSIUM ION MASS EMISSION RATE AT NOTCH 8

#### V. SUMMARY

Testing was performed to provide the ARB with data on the characterization of total particulate for various particle size fractions from a 4,400 hp GE locomotive. Two fuels were used in this study, a 0.3 percent sulfur nonroad diesel, and a CARB diesel. Sampling for particle sizing was conducted at two different operating conditions, Idle and Notch 8. Particulate characterization by particle size included volatile organic content, elemental analysis, and anion and cation levels.

Less than one percent of the particles were larger than 2.5 Fm for both fuels. The particle size distribution at Idle was monomodal, and at Notch 8 it was bimodal.

Total particulate mass emission was higher with the higher sulfur fuel for both operating conditions. Particulate emissions by particle size were similar for both fuels, down to a particle size range between 0.31 Fm to 0.17 Fm. At the smaller size ranges (0.17 Fm to 0.09 Fm, 0.09 Fm to 0.056 Fm, and less than 0.056 Fm), the CARB fuel produced lower masses of particles. This difference was also reflected in the fuel-derived VOF and the sulfate contribution to the total particulate mass. The sulfate mass emission rate was proportional to the fuel sulfur level.

Only five of 44 chemical elements were noted above the detection limit for the particle size ranges analyzed. The metal elements were mostly attributed to engine wear metals, and sulfur was associated with the fuel and lubricating oil. Except for sulfur, the metal elements were only a small fraction of the total particulate. At Idle and Notch 8, most of the detected elements were found in the larger particle size ranges (0.54 Fm to 0.31 Fm, 0.31 Fm to 0.17 Fm and 0.17 Fm to 0.09 Fm).

When operating at Idle, the 0.3 percent sulfur fuel showed a decrease in the VOF with decreasing particle size, while the CARB diesel yielded the highest VOF mass rate in the intermediate 0.31 Fm to 0.17 Fm size range. The percent of VOF attributed to unburned lubricating oil decreased with smaller particle sizes for both fuels at Idle, with the largest contribution occurring in the 0.54 Fm to 0.31 Fm size range. No consistent trends were noted for the Notch 8 condition.

For Notch 8, the average total particulate mass rate and the VOF were larger with the 0.3 percent sulfur fuel than with CARB diesel. Unburned lubricating oil derived VOF contributed about 57 percent of the VOF for the 0.3 percent sulfur fuel and about 64 percent for CARB diesel. At Notch 8, the unburned lubricating oil derived VOF was similar for both fuels, with the highest levels found in particles less than 0.056 Fm. The higher VOF levels with the 0.3 percent sulfur fuel were mostly fuel-derived VOF.

For the cations and anions, sulfate was highest with the higher sulfur fuel. Chloride, nitrate, and potassium ions were found to be only a small fraction of the total particulate. The mass emission rates for each ion were higher at Notch 8 than at Idle.
