

PART C - PUBLIC COMMENTS AND RESPONSES

NOTE:

All information which was submitted as supporting documentation for public comments on the draft Report has been forwarded to the Scientific Review Panel. However, in some cases, supporting documents have not been included here because of their length. The cases where this has been done are indicated in the report, and where a summary was provided it has been included. These documents are available upon request from:

Dear Bill:

Subject: Part B "Health Effects of Chromium" Report

On page 25 of the "Health Effects of Chromium" report, dated February 1985, the EPA Model, or "crude" model is described.

$$B = [(R-1) \times P_0] / d \quad (1)$$

where B = Potency per Unit Dose
R = Relative Risk of Cancer
P = Background Mortality Rate
d = "Lifetime averaged exposure concentration"

Subsequently, P(L,d), the "excess lifetime probabilities of lung cancer for a given dose of chromium" is defined as:

$$P(L,d) = 1 - \exp(-Bxd) \quad (2)$$

If I substitute (1) into (2), I get:

$$P(L,d) = 1 - \exp[-(R-1)P_0] \quad (3)$$

which is independent of dose.

I think something needs to be clarified here. The units of "potency" and dose seem to be different than in standard usage. There is an implicit use of dose in determining R, the relative risk of cancer, since that will be dose-dependent. The problem, however, probably lies in the use of "d" to mean two different things: In the first equation, d and R are

Received
MAY 3 1985
L. W. G.

Mr. William Loscutoff
April 29, 1985
Page 2

IT CORPORATION

used to calculate B. The best estimate of B is then used in the second equation to predict an incremental probability due to some observed ambient chromium concentration.

Incidentally, when Bxd in (2) is small, as it will be for airborne chromium, the power series expansion of the negative exponential will lead to:

$$P(L,d) = Bxd \quad (2a)$$

which is linear in dose. This really is the model I think you end up with on page 28.

Feel free to call if there are any questions.

Very truly yours,

Nick

Dear Dr. Hazelwood:

Comments on the Draft Chromium Report

Thank you for your comments and suggestions on the Draft Chromium Report. We have referred your comments to the Department of Health Services (DHS) for response. Your comments, their responses, and this letter will be included in Part C of the Report to the Scientific Review Panel. We will send you a copy of that report.

If you have any questions concerning this matter, you may contact Cliff Popejoy at (916) 323-8503.

Sincerely,

COMMENTS
ON BEHALF OF
THE METAL FINISHING ASSOCIATION OF SOUTHERN CALIFORNIA
ON THE
REPORT TO THE SCIENTIFIC REVIEW PANEL ON CHROMIUM
May 13, 1985

The Metal Finishing Association of Southern California ("MFASC" or "Association") is a nonprofit trade association of companies in the fields of metal finishing, electroplating, powder coatings, enameling, galvanizing, plating and related processes. It has almost 250 members, the vast majority of whom are job shops.¹ These comments are submitted in response to the Report to the Scientific Review Panel on Chromium prepared by the Air Resources Board and the Department of Health Services, dated March 1985. In general, after a careful review of the Report, the MFASC believes that not enough is known concerning the health effects of chromium emissions, in general, and chromium (VI) emission, in particular, to warrant regulation at this time. Unfortunately, the Association cannot offer further comment on the health impact of chromium emissions because it has not conducted independent research on this topic. In the remainder of these comments, we will highlight some confusions and inaccuracies in the Report as it relates to the metal finishing industry with the hope that a more accurate picture of the

¹ This is in contrast with captive corporate metal finishing companies.

industry and its emissions can be developed by a cooperative effort between the ARB and the industry.

Our review of the Report found five problem areas: (1) the Report incorrectly estimates the number of chrome platers; (2) the Report incorrectly assumes all chrome plating is hard chrome; (3) the Report incorrectly assumes that the emissions from the Long Beach Naval Shipyard operations are representative of chrome plating; (4) the Report incorrectly assumes that all chromic acid sold in California is used for chrome plating and generates the same emissions; and (5) the Report incorrectly assumes that all chrome plating operations are uncontrolled. Based on this confusion, the Report incorrectly concludes that the emissions from chrome plating operations in California amount to between 18 and 21 tons per year. We will take up each of these points in order.

The Report estimates that between 1,500 and 1,800 electroplaters operate in California and that if three-fourths are chrome platers there are between 1,100 and 1,300 chrome platers in California. (Report, p. I-2.) The source of the first estimate is a report by Citizens for a Better Environment. Insofar as we are aware, it is not accurate.

As noted above, the MFASC principally represents job shops, which are companies which perform on a piecework basis. It represents very few "captive" shops -- facilities owned by manufacturers facilities which solely service products they manufacture. We estimate that between 50 and 75 percent of the

metal finishers in Southern California are job shops. Of the almost 250 members of the MFASC, only 68 companies (28%) are chrome platers. Assuming, at most, an additional 70 captive shop chrome platers, that would make up to 140 chrome platers in Southern California. We estimate that in Northern California the ratio of chrome platers to electroplaters in general is similar. Based on this information, there are nowhere near 1,100 chrome platers in California. A better estimate is 300. We will attempt before the next submission to develop more detailed information on this topic. This is significant information because the inflated number of California chrome platers is used to estimate in the Report the amount of chromium emissions from the metal finishing industry in this state.

Next, the ARB assumes that all chrome plating is hard chrome. (Report, p. I-5.) By way of background, chrome plating can use either a hard chrome or decorative chrome process. For a hard chrome coating, a part is electroplated with heavy thicknesses of chromium to form a corrosion-resistant and wear-resistant surface. By contrast, decorative chrome is a process by which a part is first plated with nickel and then electroplated with a very thin coating of chromium. Emissions from hard chrome may be significantly greater than from decorative chrome due to the longer time of processing to achieve the heavier deposit. The ARB states, and we agree, that probably three-fourths of chromium use is for hard chrome and one-fourth for decorative chrome. Approximately 46 member companies in the

MFASC (19%) do decorative chrome and 22 (9%) do hard chrome. Eight companies (3%) do both. The likely difference in emissions from these two processes should be acknowledged and taken into account in the emissions calculations.

Further, the Long Beach Naval Shipyard report is used as the basis for establishing an emission factor for chrome plating. (Report, p. I-4.) This likely overestimates emissions significantly. Usually, military facilities do not have the same constraints as does private industry. Additionally, we assume that a shipyard has very large parts which generate substantially more emissions than do typical chrome plated parts. We will be able to comment further on the applicability of this facility once the ARB makes available the Long Beach Naval Shipyard report, which has already been requested.

The Report incorrectly assumes that all chromic acid sold to the metal finishing industry is used for chrome plating. (Report, p. I-4.) A large amount of chromic acid is used for chemical processes, such as dichromating, which is a process whereby a part is treated with cadmium or zinc first and then dipped in a solution of chromium salts to convert the surface metal to a chromate. It is not an electrolysis process. No bubbles are generated, such as in the case of electroplating of chromium, and no emissions are created. It is simply a quick chemical reaction. Secondly, chromic acid is also used to etch parts, both metal and plastic. Similarly, there is not the same type of buildup of bubbles or gas. We estimate that more chromic

acid is used to chemically treat or etch parts than is used in electroplating operations. Thus, the amount of chromic acid sold in California is not directly relevant to the emission report from the Long Beach Naval Shipyard or the emission of chromium into the air.

Finally, the Report calculates the emissions of chromium from the metal finishing industry based on the assumption that all chrome plating is done without air pollution controls. (Report, p. I-5.) Chrome platers located within the South Coast Air Basin -- Los Angeles, Orange, Riverside and San Bernardino Counties -- are required to have air pollution control equipment on all chromium electroplating operations because of concern by the South Coast Air Quality Management District with chromic acid mist. The District's concern rests on the possibility that without controls the sources will create a public nuisance. Chrome electroplating tanks are equipped with mist inhibitors or are controlled by air scrubbers. Air scrubbers are a closed system with virtually no emissions to the atmosphere. We believe that most facilities in the Basin are equipped with such scrubbers. The District checks the efficiency of these units at least once a year. Therefore, use of an emissions factor from the Long Beach Naval Shipyard is misleading.

The information concerning the number of chrome platers and the emissions factors to be applied led the ARB to estimate that the emissions are between 18 and 21 tons per year. As more information is developed, we believe that figure will be

shown to be seriously overstated. The Association looks forward to working with the ARB to develop a more accurate picture of the industry's contribution to the question of the chromium emissions.

611 West Sixth Street, Suite 2100
Los Angeles, CA 90017

Dear Ms. Kirwan:

Comments on the Draft Chromium Report

Thank you for the comments of the Metal Finishes Association of Southern California (MFASC). Your letter and their comments were included in Part C of the draft Report, and changes to draft Part A were made in response to their comments. This letter describes those changes and our responses to the MFASC's comments, and has been forwarded to the Scientific Review Panel as an addendum to Part C.

I am addressing your comments in the same order in which they appeared in your letter.

(1) Number of chrome platers.

Using information from surveys done by the South Coast Air Quality Management District and by the ARB, we have revised the estimate of chrome platers to 400 statewide.

(2) Hard chrome and decorative chrome plating are done in California.

The draft report presented a range of emission estimates; the upper value was based on the assumption that only hard chrome plating is done, and the lower value was based on the assumption that a combination of hard and decorative plating are done. After the draft report was released, we received information from the MFASC on the breakdown of decorative and hard chrome plating in California. Consequently the emission estimate for chrome plating

July 10, 1985

has been revised to reflect this ratio of the numbers of hard and decorative platers in California, and the emission estimate based on the assumption that all plating was hard chrome has been removed from the report.

(3) Long Beach Naval Shipyard plating operations are not representative of private industry.

The Long Beach Naval Shipyard Report used to develop emission factors for chrome plating was based on testing done in 1984, and we believe it is the best available information on chrome plating emissions. A copy of the Naval Shipyard Report was sent to MFASC representatives at their request on May 17, 1985; as of July 5, ARB staff had not received MFASC comments on that report. After the MFASC has reviewed the Naval Shipyard Report, ARB staff would welcome specific information and suggestions to improve emission estimates.

(4) Not all chromic acid sold to the metal finishing industry is used for chrome plating.

The draft report states that "the largest supplier of chromic acid in the United States estimated that 1,500 tons of chromic acid were sold in California in 1984 for chrome plating usage" (draft Report, page I-4). The estimate of chromic acid usage was for chrome plating only and did not include any other uses.

(5) Emission estimates are based on the assumption that all chrome plating is done without air pollution control.

Emissions from chrome plating were calculated based on the assumption that no controls are used on chrome plating operations, because there are no air quality regulations which specifically restrict hexavalent chromium emissions from chrome platers. Any controls in place were designed to control chromic acid mist emissions from a nuisance standpoint, as you pointed out, and were not based on the long-term health effects of hexavalent chromium exposure. The fraction of chrome plating operations which employ emission controls, and the efficiency of those controls, is not known. To provide a range of estimates, we have revised the report to include an estimate based on the theoretical assumption that all chrome platers have controls which are 92 percent efficient. This was the control efficiency of wet scrubbers reported in the Long Beach Naval Shipyard Study. We believe that the efficiency of such controls in industry will be lower than this, but that 92 percent is a technically achievable level of control, and represents a theoretical lower-limit emission estimate. The estimate of emissions based on the no-control assumption has been retained, and represents an upper limit value.

B. J. Kirwan

Dear Mr. Loscutoff:

SUBJECT: Report to the Scientific Review Panel on Chromium

Southern California Edison Company has reviewed the document entitled "Report to the Scientific Review Panel on Chromium" (Parts A and B) and would like to submit these brief comments on several important issues which are addressed in this report. These issues include the following:

Exposure Estimates - In the absence of exposure data for hexavalent chromium, a risk assessment cannot be performed at this time and chromium should be reclassified as a "Level 1B" compound since this essential information is not yet available.

Emissions Estimates - Emission estimates from sources which pertain to the electric utility industry have been overestimated due to certain assumptions and methods used in these calculations.

Risk Estimates - The unit risk estimates for hexavalent chromium are being developed from epidemiological studies of widely differing quality. These differences should be reflected in the choice of studies used to develop these risk estimates. We also feel that the boundaries on the estimates developed from these studies should be differentiated from statistical confidence limits since they result from a lack of data rather than the uncertainty inherent in a series of observations.

These issues are described in more detail below.

MAY 15 1985
3

EMISSIONS INVENTORY

Although this is not the final inventory which may be used to develop control strategies for chromium, it is important that emissions estimates are at least reasonably correct. Several errors are evident in the methods used to calculate chromium emissions from electric utility sources such as cooling towers and residual fuel oil combustion.

Fuel Oil Consumption

The calculations for residual fuel oil burned within California are inaccurate. The State's petroleum tracking system does not differentiate between oil burned in California and that sold for vessel bunkering which will be burned outside of California. Federal data indicates this is a significant use of residual fuel oil in California (1). This is shown in Figure 1. In the past, ample supplies of high sulfur residual fuel oil in Southern California have tended to drive prices lower, encouraging ships to purchase enough fuel for a round trip (2). Thus while the economic data prepared by the California Energy Commission (and used by the ARB to calculate chromium emissions) indicates that there are marketer receipts for 74 million barrels of residual fuel oil supplied to California in 1983, utilities burned only about 10 million barrels, much of which was purchased in previous years (3). This lack of accounting for vessel bunkering represents a significant overestimate in emissions of chromium from residual fuel oil consumption.

Cooling Tower Emissions

Electric utilities in California are no longer using chromate additives in cooling tower water to the extent they did in the past. SCE has not used these additives since 1982, and other utilities have reduced, or are in the process of completely phasing out, the use of these compounds. The emissions estimates for cooling towers included in the chromium report are, therefore, probably too large, since it was assumed that these compounds are used in approximately 20 percent of the utility industry cooling towers.

The combined effects of these assumptions with regard to residual fuel oil consumption and the use of chromium additives in cooling towers is to overestimate chromium emissions from electric utility sources by a substantial amount. The methods used to calculate these estimates should be reevaluated.

Figure 1. DELIVERIES OF RESIDUAL FUEL OIL BY USE IN CALIFORNIA
 (REFERENCE: PETROLEUM SUPPLY ANNUAL, 1983)

TRACE ELEMENT SPECIATION

The health assessment portion of the chromium document points out the differences in toxicity of various chromium compounds, particularly the difference in carcinogenic potential between trivalent (Cr^{+3}) and hexavalent (Cr^{+6}) chromium. The exposure data essential for conducting a risk assessment relates human population exposure to airborne hexavalent chromium in California. This information is not currently available because: a) there are no validated methods for differentiating between Cr^{+3} and Cr^{+6} at the low concentrations observed in ambient air, and b) given the lack of measurement techniques, the necessary ambient monitoring of Cr^{+6} has not been performed. Speciation techniques have been developed for workroom air (4) and progress has been made in speciating emissions from ferrochrome smelters (5). However, the dusts emitted from these smelters contain several percent chromium by weight. Samples of particulates from ambient air and sources emitting lesser amounts of chromium may contain only microgram per gram quantities. The techniques used on smelter dust might also work at concentrations 1000 times lower, but these techniques must be tested and extensively validated before they can be used in an air quality monitoring program. When these techniques have been validated then the measurements of Cr^{+6} can be made in ambient California air.

RISK ESTIMATES

Earlier risk assessments of toxic air contaminants by DHS have examined different risk estimates, and then made the policy decision to present a "conservative range of estimates" to the risk managers at the ARB. This was not the approach taken with chromium. A table of risk estimates was extracted from the EPA's health assessment document on chromium and these were presented as if they are all equally valid. This treatment of the data is inappropriate, as outlined below.

Comparative Quality of the Studies

All epidemiologic studies have some problems which cause uncertainty in the results. Some studies are considered more reliable because of the size of the study group, the quality of exposure information, and the thoroughness in tracking subjects who leave the work place. The more reliable studies are generally given more weight for developing risk estimates. EPA considered the Mancuso study more reliable than the others and this was reflected in the risk estimate they chose from all those which were calculated. Figure 2 shows the wide range of risk estimates presented by DHS and these can be compared with the estimate chosen by EPA (1.2×10^{-2} per lifetime $\mu\text{g}/\text{m}^3$ exposure). Specifically EPA stated that the studies by Langard (6), Axelsson (7) and Pokrovskaya are "less adequate than the

RANGE OF UNIT RISK ESTIMATES
PRESENTED BY DHS AND EPA

Figure 2. Block Chart of Unit Risk Estimates Derived From Three Studies. (comp= competitive risk, all others= crude model).

Mancuso study for purposes of risk assessment" and that the deficiencies in these studies tend to overestimate the risk. DHS should state why they do not agree with EPA's assessment of the quality of these studies for purposes of developing risk estimates.

The major problem with the Langard (6) and Axelsson (7) studies is the quality of the exposure data. These problems are recognized by the authors. Axelsson et al. state;

"The information on levels of chromium exposure in different parts of the industry was based on approximations, and no measured data existed for the period when a possible occupational cancer could have been induced."

"The estimated exposure data should not be used to construct general dose response relationships or to define threshold values." [emphasis added]

Langard et al. have made similar statements;

"In the present investigation one can only guess at what level the exact chromate concentration has been in previous years."

The EPA Health assessment document on chromium also notes problems with respect to the characterization of the worker cohort in the study by Pokrovaskaya.

While the studies cited above may be useful for purposes of comparison, quantitative risk estimates should be based on the highest quality epidemiologic studies available.

Uncertainty in Risk Estimates

The parameters of interest in toxicological and epidemiological studies, such as exposure and observed responses, are known to vary. This variation can be described in statistical terms, e.g., a mean and the confidence intervals around the mean. These techniques are useful in risk assessment because they can provide an indication of the uncertainty around a risk estimate.

The real parameters of interest may be essentially unknown in some cases. In the Axelsson study, for example, exposure "data" were based on estimates and approximations rather than on actual measurements. One can subjectively estimate a possible range of a variable, but the estimate has little statistical validity and cannot provide the same kind of information as a confidence interval. This type of expert "guess" must be distinguished from statistical confidence limits based upon

multiple observations (such as those presented by DHS for benzene and other toxic air contaminants reviewed to date.)

Another technique for dealing with a lack of data is to use the highest and lowest values of a parameter which were observed to "bound" the analysis. In the Langard study, 89 air measurements of hexavalent chromium were taken to characterize the workplace environment. In deriving upper and lower bounds on risk for hexavalent chromium, both EPA and DHS have assumed that all workers were exposed to either the highest, or conversely, the lowest concentration observed in all of these samples. These calculations provided the lowest and highest estimates on carcinogenic potency respectively. This type of bound or limit must also be distinguished from statistically derived confidence limits. While such estimates may be interesting for comparison, risk estimates which are to be used for risk assessment studies should be based upon the best estimates of individual worker exposure or the best estimates of the overall exposure to the worker population.

Comparison of Risk Estimates With Observed Mortality

One way to judge whether the risk estimates have any bearing on reality is to compare the predicted lung cancer mortality with the observed rates. The annual mortality rate for lung cancer in California is about 40 per 100,000. In a population of 10,000,000 people (such as the South Coast Air Basin) we would expect an annual cancer mortality rate of 4,000 per year. If we used the upper limit of risk presented in the DHS report on chromium, as many as 2,285 cancers would be due to chromium exposures. This is an extraordinarily high estimate of risk and is clearly erroneous in light of the fact that smoking is considered to be responsible for the majority of lung cancer cases.

CONCLUSIONS

SCE recognizes the desire of the ARB to proceed with the review of toxic air contaminants of concern in California in a timely manner. However, it appears that in the case of hexavalent chromium, the fundamental data necessary for conducting a population exposure assessment is not yet available. The risk assessment cannot proceed until methods for the speciation of hexavalent chromium in ambient air have been validated and ambient monitoring data have been obtained. Since the DHS health assessment indicates that hexavalent chromium is the form most likely to be carcinogenic in man, we suggest that hexavalent chromium be listed as a "Level 1B Compound" (a compound for which "significant additional information is pending") until ambient monitoring techniques have been developed and an adequate exposure assessment can be performed. The ARB has conducted a risk assessment assuming that all

airborne chromium is hexavalent. This assumption is inappropriate and should be discontinued.

We also suggest that DHS focus only on those studies with reliable exposure data when calculating risk estimates for hexavalent chromium and that the best estimates of worker exposure to hexavalent chromium (rather than extreme limits) be used for calculating risk estimates.

Methods for calculating emissions estimates from residual oil combustion and cooling tower emissions should also be reviewed for accuracy since they appear to overestimate actual emissions by a significant amount.

Sincerely,

Edward J. Farley

Rosemead, CA 91770

Dear Dr. Faeder:

Comments On Draft Chromium Report

Thank you for your comments on the Draft Chromium Report. Your comments on Part B have been referred to the Department of Health Services for response, which, along with your comments and this letter, will be included in Part C of the Report to the Scientific Review Panel on Chromium. We will send you a copy of that report. Our responses follow the same headings you used in your letter.

(Summary of Issues)

EXPOSURE ESTIMATES:

There are data available which have been used to estimate exposure to total and to hexavalent chromium. U.S. EPA National Aerometric Data Bank data for total chromium, were used to assess exposure to total chromium. ARB data on ambient hexavalent and total chromium concentrations were used to estimate excess cancer risk due to ambient hexavalent chromium. We believe that these data establish the presence of chromium and chromium(VI) in the ambient air of California to a degree sufficient to justify listing chromium(VI) as a toxic air contaminant.

June 16, 1985

EMISSION ESTIMATES:

The emission estimates for sources related to the electric utility industry we made using data from several independent sources. We agree that an improved emission inventory will be necessary in any control development process for chromium(VI). Your specific comments on our emissions estimates are discussed below

FUEL OIL CONSUMPTION:

Since the draft Report on Chromium was released, we realized that the residual oil consumed by vessel bunkering was not taken into account when chromium emissions were estimated. However, there are no available data to estimate how much residual oil was consumed by vessel bunkering in 1983. Therefore we revised our calculations as follows: Residual oil consumption for non-utilities was estimated based on 1981 data in ARB's Emission Data System and the consumption of residual oil by electric utility industry in 1983 was assumed to be 10 million barrels as estimated by SCE. This changes the estimated consumption from 74 million barrels to 49.2 million barrels. The revised calculations result in an emission estimate of 5.1 tons of chromium from residual oil combustion in 1983. In another method, chromium emissions were calculated as a fraction of particulate matter emissions. This approach yielded an estimate of 20 tons of chromium per year. These changes have been reflected in the Report and are discussed in Appendix C of Part A of the Report.

COOLING TOWER EMISSIONS:

We recognize that the electric utility industry in California may not use chromate additives in cooling tower water as extensively as it did in the past. However, chromium emissions from cooling towers were calculated based on the best available data for inventory year 1981 and/or 1979. Lower and upper estimates of 0.23 to 9.2 tons per year were also given in the Report. Therefore, without more specific information on the actual number of cooling towers or concentration of chromium(VI) for all utilities, we think the range given in the Report is the best estimates at this time. We will be trying to get more current and specific information on chromate use in cooling towers in the near future. We, therefore, would like to work with SCE and other utilities to obtain the best information available for future estimates.

TRACE ELEMENT SPECIATION:

We recognize that, because the DHS has indentified dose-response relationships for airborne chromium(VI),

June 18, 1985

information on hexavalent chromium exposure from ambient air provides the most accurate assessment of the health impact of atmospheric chromium. There are limited data available on ambient concentrations of chromium(VI) in California; we have used these data in revising the overview to include an estimate of the health impact of atmospheric hexavalent chromium. Methods do exist to differentiate between chromium(VI) and total chromium at ambient levels. We recognize that the methods for determining chromium(VI) and total chromium at low concentrations in ambient air have not yet received extensive evaluation. ARB method 106, Procedure for the Sampling and Analysis of Atmospheric Hexavalent Chromium(VI), is based on validated methods for the determination of hexavalent chromium in workplace air, and water and wastewater samples. We have included a copy of Method 106 in Appendix D of Part A. A limited interlaboratory study of this method has shown agreement within 25 percent. Method development of a chromium(VI) analytical method is presently being done by the Inorganic Toxics Analytical Subcommittee of the Toxics Air Monitoring Technical Advisory Committee (TAMTAC) which is comprised of technical representatives of Federal, State, and local air quality and public health agencies.

Chromium(III) is determined by difference between total chromium and chromium(VI). Total chromium measurements used in the exposure assessment were done using a variety of analytical methods, including x-ray fluorescence (XRF) methods similar to ARB method 105: Procedure for the Sampling and Analysis of Total Atmospheric Chromium, Lead, Manganese, and Nickel. We have included a copy of this method in Appendix D of Part A. The ARB's Haagen-Smit Laboratory Division has characterized the accuracy of Method 105 as $\pm 2 \text{ ng/m}^3$, or $\pm 10\text{-}20$ percent at the levels of $10\text{-}20 \text{ ng/m}^3$ of total chromium observed in the ambient air of California.

We believe the available information on atmospheric levels of total and hexavalent chromium in California quantitatively establishes the presence of these species in ambient air to the extent necessary to justify listing chromium(VI) as a toxic air contaminant.

The ARB is working to better characterize ambient levels of chromium(VI) in California. As more temporally and spatially representative data on chromium(VI) concentrations in the state become available, it will be possible to make a more precise estimate of the health impact of ambient chromium(VI).

CONCLUSIONS:

We believe, for the reasons stated above, that sufficient evidence of population exposure to ambient chromium(VI) exists to require evaluation of chromium(VI) as a

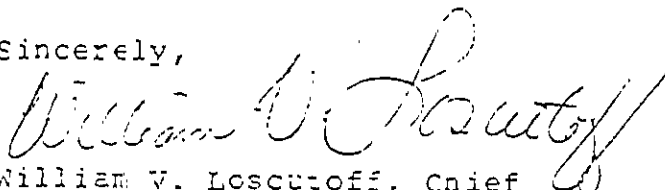

June 18, 1995

toxic air contaminant. We also believe based on the health effects information supplied by the DHS and usage and emission estimates, that chromium(VI) should be listed as a toxic air contaminant and treated as a substance having no carcinogenic threshold level.

We have deleted risk estimates based on the assumption that all ambient chromium is hexavalent, and have included revised risk estimates based on measured ambient concentrations of hexavalent chromium. As you requested, we have reviewed the methods used for calculating emission estimates from residual oil combustion and cooling towers as described previously in this letter. Based on information which you provided, we revised the emission estimate for chromium emission from fuel oil consumption.

Again, thank you for your comments. If you have other questions, please contact Cliff Popejoy at (915) 323-8503, of my staff.

Sincerely,

William V. Loscutoff, Chief

RE: Report to the Scientific Review Panel on Chromium

Dear Mr. Loscutoff:

The California Council for Environmental and Economic Balance (CCEEB) is a nonprofit organization whose board of directors include leaders of business, organized labor, and other public interest groups. CCEEB has reviewed the report by the California Air Resources Board (ARB) and the California Department of Health Services (DHS) to the Scientific Review Panel on chromium dated March 1985, and is presenting the following comments for your consideration.

In summary, the Council believes:

- (1) The risk assessment should be restricted in scope to include only chromium (VI) since this is the only species that has been associated with carcinogenicity in humans and animals.
- (2) A more appropriate range of risk of the cancer potency of chromium (VI) is 8.3×10^{-4} to 1.3×10^{-1} .
- (3) The ARB/DHS should review the studies used to determine the risk associated with chromium (VI) exposure and should focus on those studies with the most valid data when developing risk estimates. The report should more clearly state the quality problems associated with the studies chosen for inclusion in the document and the uncertainties these problems impose on the resultant risk estimates.

We believe a significant deficiency of the report is the lack of distinction between the different chromium species when drawing conclusions on the risk associated with exposure to chromium. In Part A of the report (Overview,

May 13, 1985

Part II., Page 6, Paragraph 2) ARB states that "Because toxicological data implicating chromium (III) as a carcinogen are weak, and because there is strong evidence that highly insoluble chromium (VI) compounds are carcinogenic, the DHS identifies chromium (VI) as a human carcinogen and provides dose-response relationships." ARB concludes that (Overview, Part IV., Page 11, Paragraph 1) "...we recommend that chromium (VI) be listed as a toxic air contaminant and be treated as a substance having no carcinogenic threshold." The Executive Summary of the Part B Health Effects Assessment (Page 3), however, states, "The DHS recommends that the ARB take the increased lifetime carcinogenic risk from exposure to chromium as falling in the range of 3.0×10^{-3} to 9.3×10^{-1} per microgram per cubic meter." There is no indication whether the DHS is referring to total chromium or chromium (VI) in this key statement of the Summary. It should be clearly stated that this range assesses risk from chromium (VI) exposure, derived from chromium (VI) dose-response curves.

The ARB then uses this range of risk estimates (3 to 930 per ug/m^3 /million people) and applies it to ambient air quality data representing the total chromium present in California's ambient air (since there are no validated methods for differentiating between chromium (VI) and chromium (III) at the low concentrations present in ambient air). This is clearly inappropriate, since the very conservative chromium (VI) risk estimate applied to this broad air quality data base may greatly overstate chromium risks in California.

Preliminary data (which should be validated before any conclusions are drawn) suggest that only about one-third of ambient total chromium may be in the hexavalent form, according to Part A of the ARB report. Applying the DHS derived risk estimate to the ambient chromium data in the ARB report, therefore, overstates the risk by a factor of three or more. Clearly the report needs to be made consistent. We believe the focus should be on chromium (VI), since this is the only species that has a defensibly demonstrated relationship with cancer. A better ambient air quality data base which expresses the concentrations of chromium (VI) found in the air over California, must be established to adequately address the risk associated with chromium (VI) exposure.

The Council further believes that the data support a different range of risk from exposure to chromium (VI). We feel that the lower "limit" of risk (3.0×10^{-3} per microgram per cubic meter for a continuous 70 year lifetime exposure) is not the lowest scientifically plausible estimate, that a still conservative lower estimate might be as low as 8.3×10^{-4} , and the actual risk as low as zero. As can be seen from Attachment C of the enclosed critique performed by Roth Associates, this value is the lower 95% confidence limit of relative risk obtained when the best estimate of cancer potency from the Mancuso study (1.4×10^{-4}), which is considered by ARB/EPA to be the most scientifically validated of the epidemiological assessments, is adjusted for smoking, exposure, and relative risk. We further feel that a more appropriate upper bound on risk is the most conservative of the best estimates of cancer potency, which comes out to be $1.3 \times$

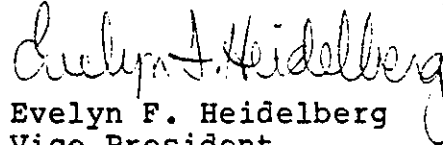

May 13, 1985

10^{-1} in the Langard et al study (see Attachment A). The Council therefore believes that the range of risk from exposure to chromium (VI) (i.e., the cancer potency) should be expressed as 8.3×10^{-4} to 1.3×10^{-1} . The Roth Associates' assessment details the data supporting this broader range. This report also expresses some of the concerns we have with the quality of the available epidemiologic data associating chromium (VI) with cancer that the EPA and the DHS relied on when performing their risk assessments, the validity of the use of some of this data (i.e., the negative Langard et al and the Axelsson et al studies), and the uncertainties that we feel should be more clearly expressed when data of somewhat questionable quality must be included in risk estimations.

CCEEB believes that with these additional qualifications to the report, the intent of AB 1807 will be met. That is, the availability and quality of data on health effects, and the range of risk to humans from exposure, will be appropriately represented to assist the Board in determining whether to list chromium as a toxic air contaminant, and if listed, in making risk management decisions with respect to chromium emissions in California.

The Council and its members appreciate the opportunity to submit these comments.

Very truly yours,

Evelyn F. Heidelberg
Vice President

A. INTRODUCTION

This report contains an assessment of some of the conclusions in the California Air Resource Board (CARB) document entitled "Health Effects of Chromium", (February, 1985). The CARB report evaluates both the toxicological and epidemiological data on hexavalent (Cr VI) as well as trivalent (Cr III) chromium. On the basis of animal studies CARB concluded that Cr III is a "weak carcinogen" while several Cr VI compounds have demonstrated statistically significant increases in the rate of cancer. Also CARB concluded that "no direct inhalation animal studies have resulted in statistically significant increases in tumor incidence."

Despite the findings of a weak association between Cr VI and lung cancer, a critical portion of the CARB document is devoted to estimating the risk of lung cancer in human populations due to Cr VI exposures. To compute this risk CARB relied upon human epidemiological data. The objective of this report is to evaluate this risk assessment and, hence, CARB's evaluation of the epidemiological data as well. Our evaluation of the epidemiological data entailed examination of factors such as the experimental design of studies, the sample sizes, quality of data, and validity of statistical computations. The evaluation of the risk calculations consisted of an assessment of the mathematical models used in the analysis.

Scope of Report: In addition to this section, this report contains four additional sections. Section B gives an overview of CARB's results. CARB used two different methodologies to calculate the risks of Cr VI; the crude model and the competing risks model. Section C evaluates CARB's crude model calculations; Section D competing risk calculations. Finally, Section E contains our conclusions.

B. OVERALL CARB FINDINGS

CARB's assessment of chromium contains an analysis of the toxicology, epidemiology, and exposure of the substance. The heart of CARB's analysis, however, involves the calculation of the risk of lung cancer mortality due to lifetime exposure of hexavalent chromium (Cr VI). The indicator that CARB used to assess this risk is "cancer potency" or the added risks

associated with each 1 ug/m^3 increment of lifetime exposure to Cr VI. CARB relied on four studies and two different mathematical models to calculate cancer potencies. The studies are Mancuso (1975), Langard et al., (1980), Axelsson et al., (1980), and Pokrovskaya (1977).

The mathematical models that CARB relied upon are the competing risk and the crude models. Both the competing risk and the crude models were applied to the Mancuso data, but only the crude model was applied to the three other studies. Also for each study CARB calculated a lower, upper, and best estimate of unit risk. In total, fifteen different scenarios were examined, but in one case there was insufficient data to complete the analysis. CARB's results are presented in Attachment A.

Results: It can be seen from Attachment A that CARB's estimate of the unit risk of Cr VI ranges from 9.3×10^{-1} -- the upper limit in the crude analysis of the Langard et al., (1980) data -- to 3.0×10^{-3} -- the lower limit in the competing risk analysis of the Mancuso (1975) data. Thus, even according to the most liberal estimate, the unit risk of Cr VI is at least 10^{-3} . Using CARB's best estimates of cancer potency the unit risk ranges from 1.3×10^{-1} (the crude analysis of Langard et al.'s study) to 1.2×10^{-2} (the competing risk analysis of Mancuso's study). Finally, it should be pointed out that CARB's cancer potency estimates are actually EPA derived results (Health Assessment Document of Chromium, page 7-79 to 7-97). Thus, hereafter, we refer to CARB's results as the CARB/EPA results.

C. ASSESSMENT OF THE CARB/EPA CRUDE MODEL CALCULATIONS

In the first part of this section we describe the CARB/EPA crude model calculations and in the second part we evaluate them.

Description: The general formula that CARB/EPA used for calculating unit risk was:

$$1 - \exp[-(R-1) P_0/d],$$

where R is the relative risk, P_0 is the background risk in the absence of exposure, and d is the lifetime effective dose in ug/m^3 . In cases where $(R-1) P_0/d$ is small the value of $(R-1) P_0/d$ is approximately equal to the unit risk of cancer potency.

In the analyses of all the studies the value EPA used for P_0 was 0.036, which is approximately the lung cancer mortality rate in the United States. The relative risk (R), which is the observed number of lung cancer deaths compared to the expected number, however, varied from study to study. In addition the lifetime expected dose varied.

The lifetime expected dose was taken to be the product of the average concentrations of Cr VI in the workplace and the fraction of time spent in the workplace. Mathematically, this is (exposure at workplace) x (fraction of day spent working) x (fraction of year spent working) x (fraction of years at risk) or

$$\text{Exposure at Workplace} \times 8/24 \times 240/365 \times 1/4.$$

The values CARB/EPA used for R and d and their sources are given in Attachment B.

Analysis: There are many problems with CARB/EPA's crude model calculations. Some of these are of a general nature and others deal with CARB/EPA's analysis of specific studies. Below we discuss both kinds.

General

One of the general problems is that as the name implies the crude model is extremely "crude". It is based on the unproven assumptions that (1) there is a linear relationship between lung cancer mortality and Cr VI exposures and (2) lifetime exposures can be categorized by a few selected measurements in the workplace. If either of these assumptions are incorrect then the CARB/EPA estimates of unit risk can be off by orders of magnitude.

Second, as can be seen from the following comments from the EPA Health Effects Document, even the Agency recognizes that the studies by Langard et al., Axelsson et al., and Pokrovskya are "of poor quality":

"From the quantitative risk assessment viewpoint, these studies are less adequate than the Mancuso study...In an effort to provide alternative potency estimates, the data from these less adequate studies have also been used by the CAG to calculate the potency of hexavalent chromium."

Specifics

In addition to the general shortcomings with the CARB/EPA analysis there are problems with the CARB/EPA treatment of specific studies. We outline some of these below.

1. Mancuso

At least seven problems exist with the CARB/EPA analysis of the Mancuso data. First, even according to EPA it is questionable whether the Mancuso study showed an association between Cr VI and lung cancer. This can be seen from the following comment in the EPA Health Assessment Document:

"Thus, it is questionable whether the author's conclusion with regard to a dose-response to both hexavalent and trivalent chromium is correct. Furthermore, the lung cancer death rates, which purport to show this dose-response, are based on very small numbers, and thus the finding of dose-response is probably questionable." (Page 7-54.)

It can be seen from the above that there is no basis for CARB/EPA to use the Mancuso study for assessing the risk of Cr VI.

Second, EPA hypothesized that the true dose in Mancuso might be double the dose used to calculate its best estimate. Therefore, it multiplied the best estimate by 1/2. In addition, EPA noted that it might have overestimated worker risks because it assumed similar smoking habits for workers and the general population. Because of this, it again multiplied its best estimate by 1/2. The end result, then, was to multiply the best estimate by 1/4 to obtain a lower limit. There is no justification for these assumptions, an issue of extreme importance because they alter cancer potency estimates by four-fold.

Third, from the discussion in the EPA criteria document it appears that Mancuso overestimated the relative risk of deaths due to lung cancer by a factor of 2. In Mancuso's study it was calculated that the expected proportion of lung cancer deaths out of all deaths was approximately 0.015. In the real world the rate is approximately double this amount or 0.030. Unfortunately, because Mancuso's study was not a published paper,

we could not obtain a copy of it to verify his computations. Mancuso's results were presented at a conference on heavy metals in Toronto.

Fourth, a close look at the results presented in the EPA document indicates that some of the workers in the cohort started working quite late in their life at the chromium facility. By the time they started working at the chromium facility they might have already been exposed to carcinogens at other places. This aspect of the study has not been factored into the CARB/EPA analysis.

Fifth, worker exposure was based on total chromium rather than only on those compounds known to be carcinogenic. This underestimated cancer potency. EPA estimated that this underestimation was unlikely to be more than seven-fold. To obtain an upper limit, then, EPA multiplied the best estimate by 7. Again, there is no data to support this adjustment.

Sixth, EPA states (p. 7-90) that it estimated the relative risk to be 7.2 by "combining the relative risks...in each of the age-exposure categories, weighted by the relative magnitude of person-years, as shown on table 7-19." There are, however, no relative risks in table 7-19 and it is not clear how EPA used the information in that table to obtain them. (The denominator is clearly the background rate given in this table; but the derivation of the numerator is not clear.)

Finally, EPA's calculation of average lifetime exposure is faulty, because it fails to adjust for the fact that workers are exposed for only a fraction of their lifetime. As the calculation was done, EPA assumed exposure for 100% of the individual's lifetime. This resulted in CARB/EPA's underestimation of unit risk. The degree to which it is an underestimate depends upon the fraction of years at risk which includes the period of first exposure until death. If this is L and l is the number of years actually exposed then CARB/EPA underestimated the risk by L/l .

2. Langard et al.

At least three major problems exist with the CARB/EPA analysis of Langard et al. Exposure measurements were taken in 1975, while some workers could have been exposed as early as 1928, when the ambient dust levels were much higher. Thus, the

concentrations to which workers were exposed were underestimated and the cancer potency was overestimated. Even in calculating a lower bound to cancer potency, EPA does not make any adjustments for the overestimation noted above. The Agency states that "these concentrations [.01 and .134 mg/m³] are used in our potency calculations, with the understanding that the potency so estimated can only be considered an upper bound estimate" (p. 7-93). In fact, however, EPA presents both upper and lower limits based on the above concentrations, in contradiction to its stated caveat.

Second, Langard et al., reported a relative risk which is not statistically significant ($7/3.1 = 2.26$). However, EPA arbitrarily inflated this value to 8.5 and made it statistically significant and used it to calculate cancer potency. By doing this, the Agency overinflated their unit risk estimate by six-fold. Thus, instead of 2.3×10^{-1} their best estimate should be 3.9×10^{-2} due to this factor alone.

Finally, the workers in the study were exposed simultaneously to other lung carcinogens such as asbestos and smoking. An adjustment for these factors would reduce the value of the relative risk and consequently reduce the estimate of cancer potency.

3. Axelsson et al.

There were three major problems with the CARB/EPA analysis of Axelsson et al. First, this study did not show a significant increase of lung cancer, and the Agency concluded, "and thus only the statistical upper bound of the response [relative risk] can be used in potency estimation" (p. 7-81). The use of the 95% upper bound on relative risk is absurd. There is no rationale for it (and none is given). It falsely inflates the potency estimate from a study that did not even show a statistically significant risk. The CARB/EPA best estimate of unit risk was 3.5×10^{-2} , based on the actual relative risk the number should have been 1.3×10^{-2} .

Second, there were four groups of exposed workers and one control group in the study. The EPA took only the group of maintenance workers for cancer potency estimates. The group of metal grinding sampling workers, who were supposedly at the same exposure levels as the maintenance workers in respect of

hexavalent chromium, should have also been included in the analysis. And also, the group of arc-furnace workers who were at higher levels of exposure should have been included.

Finally, it is not known how and when the levels of exposures to Cr were determined. There is an indication that there were other lung carcinogens, viz asbestos and smoking, to which the workers were exposed simultaneously.

4. Pokrovskaya

At least two major problems exist with the CARB/EPA analysis of Pokrovskaya. First, the cohort in this study is not well defined and, thus, the validity of the data is uncertain. Second, lung cancer mortality ratios were given as 4.4 for the age group 30-39 and 6.6 for the age group 50-59 among male workers. Without any justification EPA simply takes 6.6 as its estimate of the average relative risk. Based on the 6.6 value the best estimate is 9.2×10^{-2} whereas based on the relative risk of 4.4 it will be 5.6×10^{-2} .

D. ASSESSMENT OF CARB/EPA COMPETING RISK CALCULATIONS

As with Section C, this section is divided into two parts. The first part describes the CARB/EPA methodology and the second part assesses it.

Description: In calculating unit risk using the competing risk model CARB/EPA assumed that, (1) the occurrence of lung cancer mortality at a particular age follows a Poisson distribution (2) the occurrence of lung cancer increases with age and (3) the increased incidence of lung cancer due to exposure increases with age. The general model EPA used for age-specific incidence of lung cancer is

$$I(t,d) = B(t) + h(t,d)$$

where $B(t)$ is the background rate at age t and $h(t,d)$ is the rate due to dose d at age t and is assumed to have the following functional form:

$$h(t,d) = Q(d) t^{k-1} \text{ with } Q(d) = q_1 d + q_2 d^2.$$

The parameters q_1 , q_2 , and k were estimated based on the assumption that the number of lung cancer deaths at age t , X , follows a Poisson distribution with the mean value:

$$EX = N \times (B(t) + Q(d)t^{k-1}),$$

where N is the person-years associated with X . Once $h(t,d)$ is determined the lifetime risk associated with an exposure d , $P(L,d)$, can be determined as follows:

$$P(L,d) = \int_0^L \exp[-A(s)] h(s,d) \exp\{-[\int_0^s h(y,d) dy]\} ds$$

Here $\exp[-A(s)]$ is the probability of surviving to age s and L is the entire life-span possible. The entire expression under outer integral sign is the probability of surviving to age s and then dying between the ages s and $s + ds$ of lung cancer as a result of exposure to a dose d . $P(L,d)$ gives the lifetime probability of dying of lung cancer as a result of exposure to a dose d . $P(L,1)$ is the unit risk (i.e., the risk associated with lifetime exposure to a dose of 1).

Analysis: As stated above EPA based its competing risk calculations entirely on the Mancuso study to do competing risk analysis. All the problems with the Mancuso study listed above are, thus relevant in this case as well. In addition, the following other problems exist with EPA's competing risk computations.

First, EPA's competing risk formula is based on the assumption that increased incidence of lung cancer due to exposure is dose dependent and also increases with age. These assumptions, however, are not supported by epidemiological studies. Further, the dose-response value of the Mancuso study, in EPA's own words, is "questionable" and therefore, EPA's use of the Mancuso study for competing risk calculations is absurd.

Second, EPA based the value of $A(s)$ (the probability of surviving to age s) on U. S. Vital Statistics. This fails to take into account the risk factor of exposure, and is therefore, incorrect. Because risk factor data are unavailable we do not know the magnitude of error that was introduced because of this problem.

E. CONCLUSION AND RECOMMENDATIONS

In summary, CARB/EPA have analyzed the toxicological and epidemiological data on Cr VI and Cr III. With respect to Cr III CARB/EPA found hardly any evidence of an association between exposures and cancer. CARB/EPA, however, found stronger but still weak evidence of an association between Cr VI exposure and cancer. To estimate the human population risks of Cr VI exposures CARB/EPA relied upon two mathematical models (the crude model and the competing risk model) and four epidemiological studies (Mancuso, Langard et al., Axelsson et al., and Pokrovskaya).

The CARB/EPA estimates of the lung cancer risk due to each increment of 1 ug/m^3 of Cr VI ranged from 9.3×10^{-1} to 3.0×10^{-3} , with the best estimates ranging from 1.3×10^{-1} to 1.2×10^{-2} . There are, however, many serious problems with CARB/EPA's estimates which when corrected raise the question if Cr VI is a lung carcinogen at all. In any event strong indications exist that the CARB/EPA's unit risk estimates might be incorrect by several orders of magnitude.

One of the problems with the CARB/EPA analysis is that the results are not supported by the data. Two of the studies that the CARB/EPA uses in its analysis did not show any significant association between lung cancer and Cr VI (Langard et al. and Axelsson et al.). In addition, the epidemiological study EPA relies upon most heavily (Mancuso) is of "questionable quality" in the Agency's own words. Lastly, the fourth study upon which CARB/EPA relies on in its calculations (Pokrovskaya), has a population which is not well defined.

In addition, there are many problems with the EPA calculations because they fail to consider factors such as smoking and exposure to other lung carcinogens such as asbestos, critical factors in analyzing the causes of lung cancer. Furthermore, the sample sizes and quality of both the health data as well as the exposure are questionable. Moreover, there are serious questions about the assumptions underlying both the crude and competing models which could easily have altered the CARB/EPA estimates of cancer potency by orders of magnitude.

Finally, given all the problems with the data it would be highly speculative to estimate the cancer potency of Cr VI from

the studies and models discussed in the CARB/EPA report. Despite this we have tried to adjust for some of the quantitative problems with the CARB/EPA calculations of cancer potency. In this analysis we started with the CARB/EPA best estimate of cancer potency (based on the Mancuso data and the crude model calculations) and adjusted for the following factors: smoking, exposure, and relative risk (Attachment C). A discussion of these factors is given in the Mancuso section of this report.

As can be seen from Attachment C the CARB/EPA best estimate of cancer potency is 1.4×10^{-2} . Adjusting for smoking alone reduces the best estimate to 7.0×10^{-3} , for exposure alone to 7.0×10^{-3} , and for relative risk alone to 4.8×10^{-3} . Adjusting for all three factors simultaneously reduces the cancer potency to 1.2×10^{-3} . In addition, if the lower 95% confidence limit of relative risk is used then the cancer potency is 8.3×10^{-4} . Caution should be observed, however, in overinterpreting these values because they are based on highly questionable data and assumptions. Furthermore, they neglect to consider factors which we were unable to quantify. These latter factors might be of greater importance than the variables for which we adjusted.

In conclusion, the CARB/EPA best estimate of cancer potency ranged from 1.4×10^{-2} to 1.3×10^{-1} . Adjusting for some of the quantitative problems with the CARB/EPA analyses we obtain a range of 1.3×10^{-1} to 8.3×10^{-4} . This range, however, fails to take into account several factors which might extend the lower end of the range by several orders of magnitude.

AIR RESOURCES BOARD

1102 G STREET
P.O. BOX 2815
SACRAMENTO, CA 95812

June 13, 1985

Ms. Evelyn F. Heidelberg
Vice President
California Council for Environmental
and Economic Balance
1512 - 14th Street
Sacramento, CA 95814

Dear Mr. Heidelberg:

Comments on Part A of the Draft Chromium Report

Thank you for your comments and suggestions on the Draft Chromium Report. The Department of Health Services will prepare responses to your comments on Part B. Those responses, this letter, and your comments will be included in Part C of the Report to the Scientific Review Panel. We will send you a copy of that report. I am responding to your comments in the same sequence as in your letter.

Several people commented, as you did, that the application of dose-response data for hexavalent chromium to total ambient chromium concentrations provides estimates of excess cancer risk which, because they represent worst case or upper bound estimates, are unrealistically high. We have revised the overview to include estimates of excess cancer risk which reflect current knowledge of ambient hexavalent chromium concentrations. The resulting risk estimates are approximately one-third the value of the upper-bound estimates.

Please note that the Department of Health Services has revised the upper-bound dose-response relationship, and that the ranges of excess cancer risk have been changed accordingly.

We recognize that the methods for determining chromium(VI) and total chromium at low concentrations in ambient air have not yet received extensive evaluation. ARB method 106, Procedure for the Sampling and Analysis of Atmospheric Hexavalent

June 13, 1985

Chromium(VI), is based on validated methods for the determination of hexavalent chromium in workplace air, and water and wastewater samples. We have included a copy of Method 106 in Appendix D of Part A. A limited interlaboratory study of this method has shown agreement within 25 percent. Method development of a chromium(VI) analytical method is presently being done by the Inorganic Toxics Analytical Subcommittee of the Toxics Air Monitoring Technical Advisory Committee (TAMTAC) which is comprised of technical representatives of Federal, State, and local air quality and public health agencies.

Chromium(III) is determined by difference between total chromium and chromium(VI). Total chromium measurements used in the exposure assessment were done using a variety of analytical methods, including x-ray fluorescence (XRF) methods similar to ARB method 105: Procedure for the Sampling and Analysis of Total Atmospheric Chromium, Lead, Manganese, and Nickel. We have included a copy of this method in Appendix D of Part A. The ARB's Haagen-Smit Laboratory Division has characterized the accuracy of Method 105 as $\pm 2 \text{ ng/m}^3$, or $\pm 10\text{-}20$ percent at the levels of $10\text{-}20 \text{ ng/m}^3$ of total chromium observed in the ambient air of California.

We believe the available information on atmospheric levels of total and hexavalent chromium in California quantitatively establishes the presence of these species in ambient air to the extent necessary to justify listing chromium(VI) as a toxic air contaminant.

The ARB is working to better characterize ambient levels of chromium(VI) in California. As more temporally and spatially representative data on chromium(VI) concentrations in the state become available, it will be possible to make a more precise estimate of the health impact of ambient chromium(VI).

Again, thank you for your comments. If you have any questions, please contact Cliff Popejoy of my staff at (916) 323-8503.

Sincerely,

William V. Loscutoff, Chief
Toxic Pollutants Branch
Stationary Source Division

cc: Peter D. Venturini.

May 6, 1985

Mr. William V. Loscutoff
Chief
Toxic Pollutants Branch
Air Resources Board
Attention: Chromium
P. O. Box 2815
Sacramento, California 95812

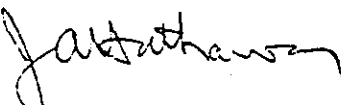

Dear Mr. Loscutoff:

Allied Corporation would like the Air Resources Board, the Department of Health Services, and the Scientific Review Panel to consider our comments and the additional information included therein. We are attaching copies of comments provided to the United States Environmental Protection Agency dated January 15, 1985 and the assessment report by the EPA's Science Advisory Board dated January 4, 1985.

This information combined with that previously submitted causes us to believe that the unit risk estimate is far too high even using the standard conservative EPA upper bound, linear low dose model.

It is hoped that this information will be given serious consideration since it appears that public comments have not been given any significant consideration thus far in the proceedings.

Sincerely,

J. A. Hathaway, M. D.
Director - Medical Services
Chemical Sector

JAH/hmw
Enclosures

MAY 10 1985

In response to the ARB's request for comments on the draft Report, Allied Chemical submitted, with a cover letter, its January 15, 1985 comments to the U.S. EPA, and an assessment report by the EPA's Science Advisory Board dated January 4, 1985. These documents were provided to the Scientific Review Panel, and are available upon request from the Toxic Pollutants Branch of the California Air Resources Board.*

* See note on page ii.

P. O. Box 1139R
Morristown, NJ 07960-1139

Dear Dr. Hathaway:

Comments on the Draft Chromium Report

Thank you for your comments and suggestions on the Draft Chromium Report. We have referred your comments to the Department of Health Services (DHS) for response. Your comments, their responses, and this letter will be included in Part C of the Report to the Scientific Review Panel. We will send you a copy of that report.

If you have any questions concerning this matter, you may contact Cliff Popejoy at (916) 323-8503.

Again, thank you for your comments.

Sincerely,

William V. Loscutoff, Chief
Toxic Pollutants Branch

Diamond Shamrock
Chemicals Company

Technical Center

May 10, 1985

Mr. William V. Loscutoff, Chief
Toxic Pollutants Branch
Air Resources Board
Attention: Chromium
P.O. Box 2815
Sacramento, California 95812

Dear Mr. Loscutoff:

These comments are being submitted by Diamond Shamrock Chemicals Company in response to the Draft Report to the Scientific Review Panel on Chromium, dated March 1985. Diamond Shamrock is the largest domestic producer of Chromium Chemicals. Our basic products are sodium bichromate and chromic acid. Diamond's manufacturing facility, located at Castle Hayne, North Carolina, is the newest chromium chemicals manufacturing facility in the United States, being completed in 1972 and reflects state of the art process, hygiene and environmental technology. We appreciate the opportunity to participate in this evaluation of chromium. We would be glad to discuss our assessment of chromium health effects further with ARB/DHS/SRP members either in person or over the phone.

We disagree with the California Air Resources Board (CARB) recommendation that chromium (VI) be identified as a potential cancer causing toxic air contaminant with no threshold. While chromium is a measurable air contaminant, we do not feel that the body of data on the health effects associated with exposure to chromium from ambient air sources supports the Health and Safety Code Section 39655 requirement that the air pollutant "may cause or contribute to an increase in mortality or an increase in serious illness, or which may pose a present or potential hazard to human health." Although the information on chromium clearly shows that there are both acute and chronic health effects associated with overexposure, we feel very strongly that these data also indicate the presence of a carcinogenic threshold. The human body can detoxify chromium (VI) at low levels of exposure, and only when the system is overloaded is there a carcinogenic risk. As a result, we do not feel that chromium (VI) causes or contributes to an increase in mortality and/or serious illness, nor does it pose a present or potential hazard to human health at the ambient concentrations encountered in the State of California or other locations.

MAY 13 1985
[Handwritten signature]

To date, there is no convincing data showing a cause effect relationship between exposures to chromium at current ambient concentrations and cancer. The only link presented by CARB between exposure to ambient levels of chrome and cancer is a mathematical risk assessment model which by its design (linear response) required a finite cancer risk even on an exposure level of one molecule per cubic meter of air.

In general, we feel that the "Part A" report overestimates the total emission of chromium into the atmosphere from the various source segments mentioned. This is evidenced in at least two segments; that of plating and container glass manufacturing. A better inventory of emission of total & chromium (VI) for the State of California is needed.

Additional efforts should be made to estimate emissions to the atmosphere from natural sources; i.e. beach sand. There should be a comparison of natural sources with anthropogenic (man-made) emissions contributing to ambient levels. The more recent dichotomous data which indicates much lower levels of potentially respirable total chromium should be used in favor of the 1977 EPA data used by CARB to estimate ambient air total chromium. CARB also describes information on chromium (VI) ambient levels which it labels as preliminary (Page III-7, Part A) - apparently without the peer review that DHS would require on health effects data. The combined overestimate of ambient air concentrations resulting from the use of the 1977 data and using their preliminary chromium (VI) data would result in a calculated chromium (VI) ambient concentration of approximately one billionth of a gram per cubic meter of air. This is 125,000 times less than our manufacturing facilities current action level of 0.0125 mg/M³. The health record at our Castle Hayne facility has not shown a case of lung cancer during its 13 years of operation. We believe that the typical levels of exposure presently maintained at the Castle Hayne facility adequately protect the health of our employees and that these exposures represent a no-risk (or below threshold) limit over an eight hour per day, forty hour work week; exposures many times greater than current ambient air levels.

It is also noteworthy that the average daily exposure to chromium due to ambient air is approximately 800 times less than the Estimated Adequate and Safe Intake (EASI) of 200 µg/day required for good health.

Specific comments on the document have been categorized and are summarized below:

RISK ASSESSMENT

- The data of Mancuso are of limited value, particularly in that the exposures were not well characterized. Given the limitations of these data, we would expect that the statistical treatment of the available data on a matter as sensitive as estimating lung cancer death rates on exposure to industrial materials would be as rigorous as our current knowledge about statistical estimation procedures makes possible. Complete work histories were available for each worker. With such a data set it is unfortunate a statistical method was selected that smoother over worker to worker exposure differences and age differences. The analytical treatment is incapable of accommodating any data on smoking habits or race differences, both known to influence significantly lung cancer death rates. Moreover, the estimates of background lung cancer death rate was chosen from U.S. Vital Statistics for 1964. No figures are provided that would allow one to assess the effect of this choice on the estimated risk over background of lung cancer deaths among workers exposed to chromium.
- The dose-response data available from the Mancuso study and other epidemiological studies are inadequate to allow a quantitative risk assessment, linear extrapolation is not justified and therefore this precludes an evaluation of risk at low levels of exposure. In addition, substantial scientific evidence is accumulating to support the concept of a threshold for chromium (VI) carcinogenicity.
- It is disappointing to see the Department of Health Services scientists not being critical of the U.S. EPA derived risk assessment.
- The original intent of the EPA was to use risk assessment as a tool to rate the relative carcinogenic potential for various substances. The estimated lifetime risk has not changed from the very crude estimate that it really represents to an "etched in stone fact" which used inappropriately by many government agencies and can be grossly abused by non-technically trained people.
- CARB's use of the ng/M^3 unit in its estimate of lifetime risk assessment isn't consistent with the $\mu\text{g}/\text{M}^3$ exposure levels estimated by EPA. Use of nanograms per cubic meter implies present ambient air levels are a risk. This is an extrapolation of three order of magnitude beyond the data used in the model.
- A Canadian University study (McMaster University) on chromium health effects titled "Effects of Chromium Compounds on Human Health" and prepared for the Occupational Health and Safety Division of the Ontario Ministry of Labor on pages 1-4, paragraph 1.10 concludes "Dose-response data available from epidemiological and animal studies of chromium carcinogenicity are of limited value in quantitative risk assessment." A copy of this document has been included for your review.

THRESHOLD

- There is a growing amount of scientific evidence supporting the concept of a threshold for chromium (VI) carcinogenicity. Results of a lifetime study in which hexavalent sodium dichromate was given intratracheally to rats demonstrated that doses distributed over 5 days per week had a weaker carcinogenic effect than the installation of a single dose once per week. Lung tumors were found in 20 of 80 rats exposed to 1.25 mg/kg of sodium dichromate once a week. There were no tumors in 80 rats exposed to the same weekly dose given at 0.25 mg/kg of sodium dichromate 5 days per week.

The interpretation of this observation is that the defense mechanisms (physiological and/or biochemical) are capable of inactivating Chromium (VI) and a carcinogenic response occurs only when these mechanisms are overwhelmed. Even though this study is as yet unpublished, it was submitted to DHS for review. No specific mention of the report was made to indicate that its support of a threshold was even considered.

- Metabolic systems have been found to reduce the mutagenicity of sodium dichromate (Cr VI) in the Ames Test. Human gastric juice, erythrocyte lysates and S9 fractions from liver, lung and kidney cell decreased chromium (VI) mutagenicity. Mutagenicity is reduced as the Cr VI is reduced to Cr III. These findings contribute to the interpretation that: (1) the reduction by gastric juice is consistent with the lack of oral carcinogenicity for chromates and (2) the activity by erythrocyte lysates is consistent with the lack of tumors at sites distant from chrome implant sites. The activity of S9 fractions for reducing Cr VI was through NADPH-requiring pathways and recent studies suggest this pathway may be induced by exposure to low levels of chromium (VI). Since Cr III is readily trapped by cytoplasmic ligands, this phenomenon indicates an intracellular detoxification of chrome and support for the conclusion of a threshold for chromium (VI) carcinogenicity.

- Representatives of IHF from Diamond Shamrock would be pleased to discuss this study and the interpretation of its results with SRP/ARB/DHS members should it be desired.

TERATOGENIC EFFECTS

There is no human evidence that chromium compounds are associated with birth defects or other reproductive disorders, therefore Chromium (VI) should not be considered to pose a human teratogenic risk. The older animal studies which reported teratogenic effects for various chromium chemicals should be closely reviewed and reevaluated as to dosage and maternal toxicity. The definition of maternal toxicity has been a relatively crude index and recent reviews have suggested that underlying mechanisms should be investigated and employed to define "maternal toxicity" with greater precision (Khera, K.S. (1985) Teratology 31:129-153). It may be that teratogenic effects were observed in these studies only when the maternal health was adversely affected, thus compromising the conclusion of positive teratogenic response for chromium compounds.

ESTIMATE OF AMBIENT AIR CONDITIONS

- The statement that "Health effects other than cancer are not expected to occur at ambient levels (Page 6) implies that chromium (VI) exposure at ambient levels causes cancer. This has not been demonstrated. It should be reworded. The only link between cancer and ambient chromium (VI) exposures is a mathematical model predicting a risk by virtue of the model form selected (i.e. linear response).
- CARB does not present information to support its statement that controlling man-made chromium emissions will impact and reduce ambient concentrations of chromium (Page 10).
- ARB Dichot. sampling data show significantly lower ambient air levels than the 1977 EPA information used to develop ambient air estimates for California. Page III-20, #4 points this out as a potential weakness. Even though the data was collected for less than one year, these ambient levels indicate a change in air quality since 1977. The conclusion on Page III-22 is definitely not correct for total chromium. "In summary, intake of chromium from ambient air represents by far the most significant exposure route to chromium, especially for chromium (VI)." Daily intake of food on Page III-22 is shown as 90 ug/day. Inhalation would result in .24 ug/day.

EMISSION INVENTORY

The estimate emissions from the plating industry seem to be overstated. Estimates were calculated assuming all emissions were uncontrolled. A plater we contacted in California indicated that scrubbers were already required in their air basin.

Conversations with members of the container glass industry indicated that emissions from Gallo Glass do not appear typical of other green glass manufacturers.

Additional and more accurate emission and ambient concentration data for Chromium (VI) are needed before meaningful regulations can be written.

MISCELLANEOUS

The use of the relative terms - weakly and highly - to describe mutagenic effects of chromium on Pg. 1 of the DHS executive summary should not be used. The report doesn't give any indication as to how chromium compared to other mutagens.

Sincerely,

Ralph E. Temple, Manager
Research & Development
Chromium Chemicals

Dear Mr. Temple:

Comments On Draft Chromium Report

Thank you for your comments on the Draft Chromium Report. We have referred your comments on Part B to the Department of Health Services for response. Their response, your comments and this letter will be included in Part C of the Report to the Scientific Review Panel. We will send you a copy of that report. I am responding to your comments under the same headings you used in your letter.

(General Comments)

Page 2, Paragraph 3:

Because chromium found or occurring in the natural environment (i.e., chromium from non-antropogenic sources) exists in the trivalent state, as chromium(III), and because it is chromium(VI) that the DHS has identified as a human and animal carcinogen, we believe that specific efforts to estimate emissions of chromium from natural sources are unnecessary. As additional data become available on ambient total and hexavalent chromium concentrations, it will be possible to better assess the relative atmospheric levels of chromium(III) and chromium(VI).

The ARB dichotomous sampler data is lower than the EPA data used to assess exposure because of differences in sampling method. The ARB dichotomous samplers collected atmospheric

particulate matter with a diameter of 10 micrometers (μm) or less; the EPA total suspended particulate (TSP) samplers collected atmospheric particulate matter with a diameter of 50 μm or less. Therefore the ARB dichotomous data is different than the EPA TSP data because it represents a smaller size fraction of chromium-containing particles. We feel it is appropriate to use the EPA TSP data for the exposure assessment because the methods used to gather chromium concentration data in the studies used by the Department of Health Services to develop the chromium(VI) dose-response curves were not selective for particle size, and therefore more closely resemble TSP collection methods.

The ARB data on ambient chromium(VI) concentrations which was labeled "preliminary" in the draft report have been deemed final, subsequent to internal review. We recognize that the data on ambient chromium(VI) concentrations have not received peer review in the same way as health effects data used by the Department of Health Services. The sampling and analysis method used to collect the data (ARB method 106, included in Appendix D to the Report) is being reviewed by a subcommittee of an interagency technical advisory committee, the Toxics Air Monitoring Technical Advisory Committee. A limited interlaboratory study of the method showed agreement within 25%.

We believe that application of industrial workplace standards for chromium(VI) to ambient air is inappropriate, and we will continue to rely on the dose-response relationships for chromium(VI) supplied by the Department of Health Services.

If you have a formal peer-reviewed epidemiological study of the workers at your facility, please provide it to us, and we will forward it to the Department of Health Services (DHS) for evaluation.

Evidence shows that chromium ingested in food is in the trivalent state, whereas a significant portion of atmospheric chromium may occur in the hexavalent form. Because the DHS has identified chromium(VI) to be a human carcinogen, and indicated that insufficient evidence exists to classify chromium(III) as a carcinogen or non-carcinogen, and because chromium(III) is poorly absorbed from the gut, we believe that comparisons of chromium(III) ingestion in diet and chromium(VI) inhalation are unjustified.

(Specific Comments)

Estimate of Ambient Air Concentrations

Available information indicates that naturally-occurring chromium occurs in the trivalent state. There is no information

June 20, 1985

to suggest that chromium(III) emitted from natural sources (entrainment of chromium(III) containing soil, for instance) would be oxidized in the atmosphere to chromium(VI). Because there are no natural sources of chromium(VI), we believe there is a high likelihood that decreasing chromium(VI) emissions to the atmosphere will decrease ambient concentrations. We have changed the report to read "...may reduce..." instead of "...will reduce..." to reflect this.

There is a difference between EPA data and ARB data on ambient chromium concentrations because different sampling techniques were used. This has been described in more detail previously.

As you point out, a greater quantity of chromium(III) is consumed as part of the average diet that is inhaled. The statement made in the draft report that "intake of chromium from ambient air represents by far the most significant exposure route to chromium, especially chromium(VI)" is based on the difference in the health effects of ingested chromium(III) and inhaled chromium(VI).

Emission Inventory

We are unaware of any Air Pollution Control District or Air Quality Management District regulation in California which specifically limits emissions of chromium(VI) from chrome plating operations. However, controls may be required by some districts to limit emissions from platers because of potential nuisance or property damage problems. It is not well known to what extent, on a statewide basis, controls are required on chrome plating emissions, or how efficient controls in place may be. Available information on achievable chrome plating emission control efficiency has been used to provide an estimate of emissions if all chrome plating operations used controls. This estimate is included in the Report.

Information provided to us by the Ad Hoc Environmental Group of the glass industry subsequent to release of the Draft Report suggests that the emission estimates from Gallo Glass were not typical of the green-glass industry. We have revised the report to reflect this information.

Lastly, we agree that additional emission and ambient data for chromium(VI) will be an important part of any control development for chromium(VI), if chromium(VI) is listed as a toxic air contaminant

Mr. Ralph E. Temple

ATTN: Mr. William V. Loscutoff
Toxic Pollutants Branch

Dear Mr. Loscutoff:

We have reviewed the ARB Draft report on Chromium to be presented to the California Scientific Review panel and would like to offer some brief comments.

The draft is very detailed and draws on a very extensive set of references. Of concern to us as a pigment manufacturer is the fact that little distinction is drawn between the very insoluble lead chromate based pigments and more soluble materials such as calcium chromate.

We believe that there is sufficient data available on the health hazards of various chromates to suggest that lead chromate pigments are in a lower hazard class than the more soluble chromate compounds.

Epidemiological studies indicate a slight increase in respirator cancer in chromate pigment production workers. However, subsequent studies where lead chromate production was distinguished from other chromate pigment production showed no statistically significant increase in cancer from lead chromate manufacture.¹

An extensive animal study, underwritten by the Dry Color Manufacturer's Association and submitted to the ARB for inclusion in this review, shows a substantial difference in the biological effect of various chromate based products and again suggest that lead chromate based pigments (Chrome Yellow and Molybdate Orange) present a significantly lower risk of cancer than many of the more soluble chromate compounds.² Lead chromates, especially encapsulated lead chromates such as our Krolor(R) pigments, provide significantly lower soluble chrome (VI) levels than do products such as zinc chromate and calcium chromate.

MAY 14 1985

We strongly believe that this difference in hazard potential should be considered when developing regulatory levels on chromium exposure. Lead chromates are already controlled by OSHA under existing Lead Standard 29 CFR 1910.1025. Meeting lead workplace exposure limits (TWA-8 hour) of 0.05mg/m³ automatically controls Cr(VI) exposure below .01 mg/m³, based on the stoichiometry of lead chromate.

In summary, the draft report should draw a clearer distinction between the various Cr(VI) containing materials, especially in the chromate pigment area where evidence suggests that not all chromate pigments provide the same hazard.

Sincerely,

P. A. Wriede
Vice President, R&D

COMMENTS OF THE
AD HOC ENVIRONMENTAL GROUP
TO THE DRAFT REPORT TO THE
SCIENTIFIC REVIEW PANEL ON CHROMIUM

March 1985

1. Introduction

These comments are being submitted by an ad hoc group of 20 glass manufacturers, refractory manufacturers and material suppliers ("Ad Hoc Environmental Group") in response to the Draft Report to the Scientific Review Panel on Chromium ("Draft Report"), dated March 1985. Part A of the Draft Report reviews the uses of, the emissions from and the public exposure to chromium and its compounds in California. Part B of the Draft Report evaluates the health effects of chromium and its compounds. On the basis of this report, the ARB has proposed identification and control of chromium (VI) as a toxic air contaminant ("TAC") under AB 1807 without the establishment of a threshold limit.

We have been advised that at this first stage of the regulations the ARB will determine whether all chromium or chromium (VI) should be listed as a TAC and whether a threshold limit could be set. We are offering at this time, in response to the Draft Report, information and reports on chromium that may not have been available to the ARB and that we believe worthy of consideration. We recognize that this is a difficult and complex issue and hope that this information will be helpful.

At this stage the Ad Hoc Environmental Group strongly opposes regulation of any other chromium compounds, such as chromium (III), or the consideration of all chromium compounds as a TAC. Further, the Ad Hoc Environmental Group believes that a threshold emission limit can and should be set for chromium (VI) if it is identified as a TAC.

Additionally, as reviewed in more detail below, in Part A of the Draft Report, certain information about the glass industry is presented that we believe to be premature and perhaps misleading. We request that these comments and results reported concerning the glass industry be termed preliminary, if retained in the report at all.

The second stage of the regulation process, we have been informed, will concern the evaluation of specific sources of emissions to determine the reductions that could be achieved. At this stage, the ARB will work more directly with the industries involved. The Ad Hoc Environmental Group believes that the ongoing test program will prove that chromium (VI) emissions from glass manufacturing facilities in California are insignificant. When the current test program being conducted by the ARB and the industry is completed, there will be more factual information to determine whether the industry should even be included for consideration.

2. Background

Glass manufacturing is one of the oldest industries known and of key significance to the agricultural industry. Most glass is made with sand, soda ash and limestone as the primary ingredients. Other components provide color and other characteristics. Chromium is a color additive, used to make green container glass. Chromium is normally introduced in its trivalent form, as chromium (III).

3. Response to Health Effects Analysis

A significant amount of medical investigation and analysis has been evaluated by the DOHS and will be studied by the Scientific Review Panel ("SRP"). The DOHS has concluded that the health effects from the trivalent and hexavalent forms of chromium differ. The body of scientific evidence has led the DOHS to determine there is no substantial evidence implicating trivalent chromium compounds as carcinogens. (Draft Report, Part B, pp. 10-11.) To the contrary, Chromium (III) is a necessary part of the body chemistry.

Chromium (VI), on the other hand, in the opinion of the DOHS, has been associated with increased rates of cancer from injection exposure in some forms. There remains, however, further question, even among the medical community, about the validity of the test results as they apply to humans.

In this regard, we generally support the analysis of existing health effects studies provided in the Hathaway Report.¹ Dr. Hathaway concluded that the EPA Health Assessment Document for Chromium seriously overestimates the health risks associated with chromium exposure and that there is sufficient data to set a threshold for chromium exposure.

¹ Dr. J. A. Hathaway, M.D., Director - Medical Services, Allied Corporation, to Dr. Bernard D. Goldstein, M.D., Assistant Administrator, U.S. EPA Office of Research and Development. A copy is attached as Exhibit 1.

We have also reviewed other reports and documents and have found additional information which we believe is worthy of ARB and DOHS consideration, as follows:

- Table 1 - chromium levels and standards with referenced
- Table 2 - carcinogenicity of chromium compounds in experimental animals inhalation exposure with references
- Table 3 - Carcinogenicity of chromium compounds on experimental animals oral exposure with references
- Table 4 - Toxic effects of chromium compound on experimental animals inhalation exposure with references
- Table 5 - Toxic effects of chromium compounds on experimental animals oral exposure with references

These tables, along with a further list of references, is attached as Exhibit 2.

Just as important as the health effects discussion, Part A of the Draft Report is confusing because, while it recognizes the significant differences between chromium (III) and chromium (VI), its estimate of the excess cancer burden in California is based on the assumption that all ambient chromium is hexavalent (Draft Report, Part A, p. 10). If the ARB and the DOHS have concluded that only chromium (VI) has a toxic potential, then only health assessment studies relating to hexavalent chromium should be used in the determination of chromium as a TAC. The inclusion of information on total and trivalent chromium is misleading and improperly inflates exposure levels. Misleading and confusing the public, even inadvertently, on

health concerns will, in our opinion, eventually damage the credibility of the ARB, DOHS, and SRP in the eyes of the public and may potentially injure the reputation of our products.

Once chromium in a particular form, such as hexavalent, is described as toxic, there is a responsibility for the government to participate in educating the public that hexavalent chromium does not mean that all chromium is dangerous. Perhaps specific chemical terms only should be applied to the designated toxic forms.

In spite of the conclusions by the ARB staff that only chromium (VI) be listed, the Draft Report continually references chromium in general and does not separate out chromium (VI) in the industry references or sources. This is extremely significant because by blurring the lines between all chromium forms the Draft Report increases the cancer risk from chromium exposure beyond the facts. The ARB should develop accurate information about usage of chromium (VI) before it decides upon regulation as a TAC.

On a related topic, the Draft Report recommends that chromium (VI) should be treated as a substance having no carcinogenic threshold level. This is not supported by the facts or by the actions of other responsible governmental agencies. The state Occupational Safety and Health Administration ("OSHA") lists a permissible exposure limit ("PEL") for chromium (VI) at 0.05 mg/M³. The American Conference of Governmental Industrial Hygienists ("ACGIH") has also established a threshold limit value

("ILV") for chromium (VI) at 0.05 mg/M³. Federal OSHA has set a PEL for chromic acid and chromates, including chromium (VI), at 0.1 mg/M³. Finally, the National Institute for Occupational Safety and Health ("NIOSH") has a recommended PEL for carcinogenic chromium (VI) compounds of 0.001 mg/M³. The Ad Hoc Environmental Group does not have sufficient information at this time to allow it to choose between these limits. The point is that four eminent groups of administrators and scientists have already taken on the task and with available information have set a threshold limit for chromium (VI). The ARB should as well.

4. The Part A Report

In addition to general comments about listing chromium (VI) as a TAC, the glass container industry strongly believes that the data being developed shows that it as an industry should not be part of the listing effort. In this section, we will review the Part A comments concerning the glass manufacturers and our responses.

The Draft Report states that the eight green container glass manufactures in California may be a significant source of chromium emissions. (Draft Report, Part A, p. I-6). There are only six container glass manufacturers in California that use chromium compounds to produce green glass. Some of these manufacturers produce green glass only on an intermittent basis by glass furnace color change. At this time, all green glass colorant used is iron chromate or trivalent chrome.

The test results reported in the Draft Report by the ARB are suspect and additional tests are scheduled. We have been informed by the ARB that this data will not be used for any regulatory decisions. Under these circumstances, and in view of the fact that additional tests of several sources are in process and scheduled, we request that the initial reported test results be termed preliminary and be withdrawn from the Draft Report and from its conclusions.

The test reports communicated to glass manufacturers by telephone indicated levels of chromium (VI) in a range of less than one pound per year. The telephone results on other furnaces are proof that the amount of chromium air emissions are negligible and that the use of chrome bearing (trivalent) refractories in glass melting furnaces results in no significant chromium air emissions. The unsupported prior concerns of the ARB about chrome bearing refractories in glass furnaces producing toxic air emissions have not been proven incorrect by ARB testing. The use of refractories should, therefore, not be questioned from a health impact point of view.

Refractory manufacturing emissions have been studied and reported to the ARB and EPA. Four sources were tested at the Moss Landing facility for chromium emissions. Chemical analysis of the samples showed that no chromium (VI) was detected in any sample.² An industry study, including a comprehensive survey of

² Kaiser Aluminum Corporation Report, Moss Landing Magnesia and Brick Plant Chromium Air Emissions Survey, 11-21-84, Exhibit 3.

all refractory plant locations in the U.S., concluded that the principal forms of chromium used in making refractory brick do not appear to be linked with cancer and the group of materials were identified as trivalent chromium compounds from their chemical structures. Further, that exposure to trivalent chromium compounds does not cause cancer is supported by negative findings drawn from a variety of sources.³

Additionally, the table of estimated chromium emissions in California presented in Part A of the Draft Report does not list glass furnaces -- another indication of the insignificance of the source. (Draft Report Part A, p. I-5.) Similarly, since at least the fall of 1984, EPA has been considering the listing of chromium as a hazardous air pollutant under Section III of the Clean Air Act. The categories of sources for which EPA will establish emission limits ("NESHAPS") will be determined on the basis of a risk assessment, the availability of control technology and benefits of controls. In July 1983, the Office of Air Quality Planning and Standards of EPA made a request for a scientific assessment of chromium. The document, "Health Assessment Document for Chromium," lists in Table 3-6 chromium sources, emissions and risk. A copy of the Table is attached hereto as Exhibit 5. The table lists chrome plating, refractory

³ Evaluation of the Potential Health Effects of Trivalent Chromium Compounds in the Refractory Industry, Battelle Laboratories, 2-18-83, Exhibit 4.

production, chemicals production, steel production, municipal incineration, sewage sludge, incineration, ferrochrome production, cement production, ore refining, coal and oil combustion, including power plants, industrial boilers and commercial and residential heating and cooling towers -- eleven sources in all. It is significant that the glass industry was left out.

The Draft Report states that review of the "EPA-sponsored tests have indicated extensive emissions of chromium from green glass furnaces in states other than California." (Draft Report, Part A, p. I-6.) This, too, is questionable. As noted in the recent attached letter from EPA, EPA is seeking test results and information from the industry due to lack of verifiable tests and data on hand. (Exhibit 6 hereto.) Requests for data and the use of a contractor to locate data would not be occurring if tests were available to EPA.

Most importantly, there is no indication even in the quotes that there is hexavalent chrome in glass operations. If the EPA reports are speaking of trivalent or even total chrome, the quotes should not be used and incorrect references corrected.

5. Conclusion

We suggest that further study and analysis of medical reports be conducted before a decision is reached to list chromium as a TAC. We urge that the ARB carefully separate the data on the various forms of chromium. Total and trivalent

chromium studies should not be included in any analysis and condemnation of chromium (VI).

Further testing of the glass industry, which uses trivalent chromium as a green colorant and in the furnace refractories will be expensive. It will likely prove to be unnecessary and nonproductive when viewed in the light of other potential emitters. Additionally, the tests conducted and reported to date offer evidence to support nonregulation of the refractory manufacturing industry for chromium emissions. We hope that our comments will be considered in the deliberations of the Scientific Review Panel and look forward to working with the ARB and DOHS on their test program.

Washington, D. C. 20000

Dear Dr. Goldstein:

I want to thank you for the opportunity to discuss the concerns of the Industrial Health Foundation's Chromium Chemicals Environmental Health and Safety Committee regarding the Health Assessment Document for Chromium with members of EPA's Carcinogen Assessment Group. As you requested, the following comments will cover the topics which were discussed on December 21, 1984. Some additional information which has more recently been brought to our attention will also be included.

The two main issues discussed were our concerns: (1) that the unit risk estimated in the document for hexavalent chromium was higher than could be supported by all the evidence and (2) that there was inadequate discussion in the document of the scientific evidence supportive of a threshold for chromate carcinogenesis.

Unit Risk Estimate:

The unit risk for chromium was estimated using exposure information and lung cancer rates from Mancuso (1975). The exposure data presented by Mancuso was based on earlier industrial hygiene sampling by Bourne and Yee (1950). We believe there are a number of "problems" with the Mancuso data that result in an overestimate of the unit risk. Members of CAG indicated they had previously considered some of these arguments as presented in my October 1983 correspondence to the SAB and felt that the arguments would impact the final unit risk estimate by only a factor of two or three which would not be significant in terms of regulatory action. It is our contention that a combination of factors when multiplied together result in a much larger degree of overestimation of between one to two orders of magnitude. The "problems" include:

January 15, 1985

Bernard D. Goldstein, M. D.
United States Environmental Protection Agency
Washington, D. C. 20000

Unit Risk Estimate - continued -

1. Exposures were measured only in 1949 although exposure started between 1931 and 1937 and continued for some members of the cohort to 1972. Exposures in years prior to 1949 were substantially higher than in 1949 as indicated by statements quoted from the Bourne and Yee paper on page 7-83 of the Assessment Document. Data from the 1975 Mancuso paper is also supportive of such a conclusion. In Table 2 of his paper the cohort is divided into groups based on year of first hire. There is a steady decrease in the portion of lung cancer deaths in succeeding cohorts: 1931-1932 (27.5%); 1933-1934 (23.8%); and 1935-1937 (18.4%). Since deaths were followed through 1974 it seems likely that this decrease may be related more to reduced exposures over time than simply to a difference in latent periods among the cohorts.

It is also important to note that information on chromate related lung cancer from Germany was available in 1946. Technical representatives from the United States' Chromate producers visited German chromate plants following World War II and heard of the adverse lung cancer experience. Dr. Baetjer of Johns Hopkins who worked closely with Allied's Baltimore Plant also learned of this problem at about the same time through scientific contacts. In 1946, Allied performed an initial review of their mortality experience and concluded that a lung cancer problem existed. This was discussed among the three United States chromate producers who asked the Metropolitan Life Insurance Company (an insurance carrier for the producers) to conduct an epidemiology study (Machle and Gregorius, 1948). Starting in 1946 lung cancer cases were awarded Workers Compensation under stipulation by the chromate producers. Major efforts were

January 15, 1985

Bernard D. Goldstein, M. D.
United States Environmental Protection Agency
Washington, D. C. 20000

Unit Risk Estimate - continued -

initiated to control chromium dust levels in 1945 through improved work practices, personal protection, and plant modifications and continued into 1947. Discussions with individuals working in our plants indicate that very substantial reductions in chromate exposures occurred during 1946 and 1947 at United States' plants well before the facility modifications that took place in 1949 and 1950.

In 1947 over 2,500 industrial hygiene samples were taken to evaluate chromate exposures at Allied's plant. These samples were used to evaluate improvements in dust exposures based on work place controls or minor equipment modification. The average exposure level for all plant locations was 0.9 mg/m^3 of chromate as CrO_3 for an eight hour time-weighted-average. Exposure levels prior to 1946 were substantially higher than this value and exposure levels immediately after (1948-1950) were lower. Similar changes in exposure levels occurred at the Diamond Shamrock plant studied by Bourne and Yee, and the exposure levels measured in 1949 were substantially lower than those present prior to 1946.

2. The exposure estimates used in Mancuso's 1975 paper reflect exposures under normal operating conditions only (derived from data presented in Figure 1 of the Bourne and Yee 1950 paper). The much higher exposures that occurred under maintenance or upset conditions were not factored into Mancuso's mg/m^3 -year figures. According to Table 5 (Bourne and Yee, 1950) eight hour time-weighted-average exposures for maintenance workers were often 5-10 times higher than under normal operating conditions. Thirty percent of the workforce was involved in maintenance work and the higher exposures that occurred during maintenance undoubtedly impacted other production workers as well.

January 15, 1985

Bernard D. Goldstein, M. D.
United States Environmental Protection Agency
Washington, D. C. 20000

Unit Risk Estimate - continued -

3. We have been troubled with the exposures noted in Table 9 of the Mancuso paper for some time. This data, which is the basis for the unit risk estimate, seems too low considering the average 1949 work place exposure levels reported even under normal operating conditions by Bourne and Yee. Since exposures averaged over 1.0 mg/m^3 for 3 of 9 work areas and 0.4 to 0.7 mg/m^3 for 3 other areas it seemed very strange that such a small number of person years would be represented by the higher exposure groups. The ratio of person years for exposures of 6.0 mg/m^3 -years or greater compared to all exposures were $561/2837$ for ages 45-54, $414/2189$ for ages 55-64, and $164/827$ for ages 65-74. Considering that employment started between 1931 to 1937 and continued possibly until 1972 when the plant closed, it seems odd that such a high proportion of persons (as reflected by person years) would have had relatively low exposures.

Since our meeting on December 21, 1984, I asked Diamond Shamrock to check whether job assignment information had been provided to Mancuso for time periods subsequent to 1949. I discovered that such data had not been provided and that the exposures noted in his 1975 paper reflect exposures only to 1949. In evaluating Mancuso's data (page 7-83) the CAG assumed that work experience post-1949 was assigned exposure ratings based on the 1949 industrial hygiene data. In fact all post 1949 work experience is treated as zero exposure by the Mancuso paper, even though this is not indicated in the paper and one could easily conclude incorrectly (as was done by CAG) that exposure ratings included post-1949 exposures.

January 15, 1985

Bernard D. Goldstein, M. D.
United States Environmental Protection Agency
Washington, D. C. 20000

In their discussion on page 7-91 CAG indicates that they feel the Mancuso data might underestimate the actual chromium exposure by a factor of 2. We feel the underestimation is much greater than this. A 2 fold factor might be applied for lack of consideration of post-1949 exposure. Failure to factor higher exposures from maintenance work might have resulted in about a 2-4 fold underestimation of exposure. From Table 4, Bourne & Yee, (1950) maintenance time by crafts in production areas averaged 3 hours. [3 hours/8 hours] x 5-10 fold higher levels of exposure during maintenance approximately equals 2-4. We feel the actual difference in exposure between 1949 and periods before 1946 was greater than a factor of 2 and could well have been in the range of 5 fold.

When the potential factors for underestimation are multiplied together (2 x 2-4 x 5) the result is a 20-40 fold underestimation of exposure. This in turn results in an overestimation of 20-40 fold in the unit risk estimate.

The veracity of our argument is supported by an examination of Table 7-21, page 7-99 of the Health Assessment Document and a comparison of the relative potencies of benzo[a]pyrene and chromate as listed in that table with the results of the chromate intratracheal instillation study report we provided to the EPA in 1983. Our study used benzo[a]pyrene as a positive control so that carcinogenic potency can be compared directly with chromate. Benzo[a]pyrene at a lifetime dose of 350 mg/Kg produced squamous cell carcinomas in 9 of 10 rats. These tumors caused the death of the rats at about 15 months of age. Sodium dichromate at a lifetime dose of 160 mg/Kg (equivalent to 63.5 mg/Kg chromium) caused small, non-fatal squamous cell carcinomas in 6 of 80 rats noted at

January 15, 1985

Bernard D. Goldstein, M. D.
United States Environmental Protection Agency
Washington, D. C. 20000

Unit Risk Estimate - continued -

necropsy after 30 months of administration (total lung tumors, benign and malignant were found in 20 of 80 rats). Using the one-hit model (similar in results to the

linearized multistage model and easier to calculate)

$P(D) = 1 - e^{-Bdt^3}$, where t = age at tumor/life span, results in a calculation of the slope (B) for sodium dichromate (as chromium) of 0.00126 for squamous cell carcinomas or 0.00456 for all lung tumors. The slope (B) for benzo[a]pyrene is 0.053. In this study benzo[a]pyrene was 12 to 42 times more potent than sodium dichromate depending on whether all tumors or only squamous cell carcinomas are considered. This compares to Table 7-21 where chromium is 3.56 (41/11.6) times more potent. Comparing relative potencies of benzo[a]pyrene and chromates in our rat study with the opposite ratio indicated in Table 7-21 we estimate the unit risk for chromates is overestimated by 42 (12 x 3.56) to 149 (42 x 3.56) fold. This estimate compares favorably with the 20-40 fold overestimate of unit risk that we believe results from underestimates of exposure in the Mancuso work. It should also be remembered that the rat data we used in the previous calculations was for rats exposed once a week. For rats exposed to the same total lifetime dose 5 days per week no lung tumors were seen.

Evidence Supportive of a Threshold for Chromate Carcinogenicity:

We feel there is substantial evidence supporting the concept of a threshold for chromate carcinogenicity. This evidence is derived from both animal studies and biochemical studies of chromate metabolism. It is further supported by findings in human epidemiological studies. ✓

January 15, 1985

Bernard D. Goldstein, M. D.
United States Environmental Protection Agency
Washington, D. C. 20000

Evidence Supportive of a Threshold for Chroma Carcinogenicity
- continued -

In animal studies chromates produce cancers only at the site of contact (lung carcinomas from intracheal implantation or instillation and muscle sarcomas from intramuscular injection). No tumors have been found at distant sites. We believe the explanation for this observation is that hexavalent chromium is rapidly converted to trivalent chromium and that only the hexavalent form is capable of causing cancer. Carefully performed epidemiology studies have also failed to identify any excess risk of cancer in organ systems other than the respiratory tract.

The rat intratracheal instillation study that we have previously referenced found lung tumors in 20 of 80 rats exposed to 1.25 mg/Kg of sodium dichromate once a week. There were no tumors in 80 rats exposed to the same lifetime dose at 0.25 mg/Kg of sodium dichromate 5 days per week. One obvious explanation is that the animals were able to detoxify the 5 times per week dose but were not able to completely detoxify the once a week dose and hence some tumors developed.

Several studies on the metabolism and/or detoxification of chromates have been published or are in press (references and/or prepublication copies are enclosed). These studies have demonstrated that:

1. Hexavalent chromium (Cr^{+6}) is converted to trivalent chromium (Cr^{+3}) outside of target cells by saliva and gastric juice.
2. Cr^{+6} is converted to Cr^{+3} in red blood cells.
3. Cr^{+6} is converted in cytoplasm to Cr^{+3} by endogenous glutathione and other reducing compounds.

January 15, 1985

Bernard D. Goldstein, M. D.
United States Environmental Protection Agency
Washington, D. C. 20000

Evidence Supportive of a Threshold for Chromate Carcinogenicity
- continued -

4. Cr^{+6} is metabolized to Cr^{+3} in certain cells probably by DT diaphorase. This reduction is very potent in liver cells, is weaker in lung tissue but based on recent continuing research appears to be quite potent in human lung macrophages.
5. Cr^{+6} is mutagenic while Cr^{+3} is not. Trivalent chromium is an essential mineral when incorporated into glucose tolerance factor.
6. While some scientists have suggested Cr^{+3} as the ultimate carcinogen binding DNA (perhaps following reduction from Cr^{+6} in the immediate vicinity of DNA) there is some evidence that the ultimate carcinogen may be the more reactive Cr^{+5} ion (Jennette 1982). In any event, whether Cr^{+3} or Cr^{+5} is the ultimate carcinogen, reduction of Cr^{+6} to Cr^{+3} results in the practical elimination of carcinogenic risk as demonstrated by mutagenicity studies and the lack of tumors at distant sites following Cr^{+6} administration in animals.

As we discussed during our meeting this evidence does not permit quantification of the threshold or description of the dose-response curve at low doses. However, there is a firm theoretical basis for expecting a non-linear response between the administered dose of chromates and the induction of lung cancer. This is further supported by the animal carcinogenicity study results. We are interested in pursuing studies that would more quantitatively support the concept of a threshold for chromates. At our meeting you indicated that the demonstration of significant non-linearity between

January 15, 1985

United States Environmental Protection Agency
Washington, D. C. 20000

Evidence Supportive of a Threshold for Chromate Carcinogenicity
- continued -

administered chromates and the formation of chrome-DNA adducts would provide strong support for a threshold. We would appreciate a response from the CAG on how they would evaluate such data, and under what circumstances they would consider it adequate to support the concept of a threshold. Any suggestions the CAG might have regarding other studies that would be helpful in obtaining regulatory agency recognition of a threshold (assuming, of course, that the study results supported such a conclusion) would be appreciated.

Summary:

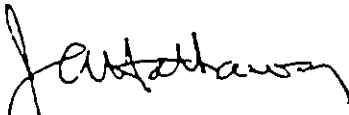

In view of the information presented in this letter regarding the substantial underestimation of exposure in the 1975 Mancuso paper, it is our opinion that continued use of the unit risk estimate presented in the Final Report Health Assessment Document for Chromium can no longer be justified. The fact that Mancuso did not consider any post-1949 exposures invalidates the unit risk estimate. The marked change in work practices in 1946-1947 following discovery of a lung cancer hazard also invalidates use of 1949 exposure data in calculating a risk estimate. Based on the fact that Mancuso's data did not include post-1949 exposure data and the marked discrepancy between the relative potencies of benzo[a]pyrene and chromates in Table 7-21 and our rat intratracheal instillation we feel that a revision or amendment to the Health Assessment Document is in order. We recommend that a unit risk assessment be calculated based on our rat intratracheal instillation study. If Mancuso's data is to be used for unit risk estimation, we recommend that appropriate adjustments be made for underestimation of exposures. If an amendment or revision is drafted we request that our position regarding support for a threshold also be discussed even if the agency does not concur with all of our interpretations of scientific data.

United States Environmental Protection Agency
Washington, D. C. 20000

I want to thank you again for the chance we had to express our viewpoints on chromium. The interchange of thoughts and ideas with you and members of the CAG appeared to be productive and I believe it lead to a better understanding of each others position. Hopefully there can be a change of position when the facts warrant it. If there are questions that arise as you or your staff review this letter and the enclosures please do not hesitate to call me for clarification or more information. My telephone number is (201) 455-4228.

Sincerely,

J. A. Hathaway, M. D.

Addendum 2

Recalculation Of Unit Risk Using Alternative Method
From Alexsson, et al.

The CAG might be tempted to argue that the Alternative (Crude) Approach for Calculating the Carcinogenic Potency of Chromium described in paragraph 7.2.3.1.5 on page 7-90 was supportive of the unit risk calculated from the Mancuso paper. However, if the exposures estimated by Mancuso were in error on the low side as we contend, the unit risk of 1.4×10^{-2} /ug/m³ calculated on page 7-90 is also in error. The subsequent calculations based on papers by Langard, et al., Alexsson et al., and Pokrovskaya et al. represent selective use of the literature. The high unit risks calculated are sometimes more the result of statistical uncertainty in the 95% upper bound limit due to small number of cases than truly high risk.

For example using the Alexsson et al. paper, if all exposed workers are considered as opposed to maintenance workers only then 6 lung tumors were seen versus 5.2 expected. Three of these lung tumors were mesotheliomas (two in maintenance workers and one in arc-furnace workers). The 95% upper confidence limit of the relative risk for lung cancer for 3 observed (6 lung tumors minus 3 mesotheliomas) and 5.2 expected is 1.48 (7.7/5.2). Using the formula to calculate unit risk $B = (1.48-1) \times 0.036/6.95 = 2.5 \times 10^{-3}$ /mg/m³ where the "standardized dose" is calculated from an eight hour TWA exposure of 0.13 mg/m³ of hexavalent chromium which is a weighted average of the exposures from Table 1 in the Alexsson paper based on 622 arc-furnace workers with exposure₃ of 0.25 mg/m³ and 315 maintenance workers with exposure of 0.05 mg/m³ and 543 transport, metal grinding, and sampling workers with exposure of 0.03 mg/m³.

The above calculated unit risk is 14 times lower than the unit risk calculated from selective use of only the maintenance workers in the Alexsson study. Even this relatively high risk is based on a negative study where the exposed workers had a higher proportion of smokers and some workers had concurrent exposure to asbestos; both factors which may have exaggerated the number of lung cancers.

Average concentration in marine plants	1.0 ppm	NAS, 1974

TABLE 1 - Continued

<u>Background Levels</u>	<u>Concentration/level</u>	<u>Reference</u>
Concentration in marine animals	0.2-1.0 ppm	NAS, 1974
Average concentration in land plants	0.2 ppm	NAS, 1974
Average concentration in mammals	0.3 ppm	NAS, 1974
Concentration in drinking and surface waters in U.S.	0.001-0.112 ppm (mean=0.0097 ppm) (mean=0.0023 ppm)	NAS, 1974 CEC, 1978
Annual mean concentrations in urban air (0.01 ug/m ³ =detectable minimum)	0.01-0.03 ug/m ³	NAS, 1974
Annual mean concentration in rural air	Seldom reaches 0.01 ug/m ³	NAS, 1974
National average for Cr in air	0.015 ug/m ³ (max=0.350 ug/m ³)	NAS, 1980a
Air concentration in Jasper National Park, Alberta, Canada	0.00032 ug/m ³	Rahn, 1971
Air concentration in Riding Mountain National Park, Manitoba, Canada	0.00092 ug/m ³	Rahn, 1971
Air concentration in Prince Albert National Park, Saskatchewan, Canada	0.0011 ug/m ³	Rahn, 1971
Concentrations of professional industry exposures	10-200 ug/m ³	CEC, 1978
Concentration in cigarettes	0.0014 ug/cigarette	Norman, 1977
<u>Tissue Distribution</u>	<u>Concentration/level</u>	<u>Reference</u>
Concentration in plasma	0.001-0.005 ppm	Doisy et al., 1976
Concentration in urine	<0.001 ppm	Guthrie, Wolf, and Veillon, 1978
Concentration in human hair	0.2-2.0 ppm	Mertz, 1969

TABLE 1 - Continued

<u>Tissue Distribution</u>	<u>Concentration/level</u>	<u>Reference</u>
Concentrations in persons in New York/Chicago area:		
> lung	0.7 ppm	Schroeder, Balassa, and Tipton, 1962
> liver	0.27 ppm	
> kidney	0.09 ppm	
Concentrations in persons in Denver area		
> lung	0.14 ppm	Schroeder, Balassa, and Tipton, 1962
> liver	0.03 ppm	
> kidney	0.04 ppm	
Total human body content	<6 mg	Burrows, 1978
<u>Intake and Excretion Levels</u>	<u>Concentration/level</u>	<u>Reference</u>
Daily intake from diet	5-400 mg	NAS, 1974
Daily intake from "typical" U.S. diet	37-130 ug (avg.=62ug)	NAS, 1980a
Estimated mean daily intake in man from		
> food	280 ug	NAS, 1974
> water	4 ug	
> air	0.28 ug	
Urinary excretion per day	7-10 ug	NAS, 1974
<u>Nutritional Requirements</u>	<u>Concentration/level</u>	<u>Reference</u>
Necessary daily intake of Cr		
> furnished in the best available form	40 ug	NAS, 1974
> supplies in form of inorganic salts	2000 ug	
Estimated adequate and safe daily intakes		
> Infants 0-0.5 yr	10-40 ug	NAS, 1980b
0.5-1 yr	20-60 ug	
> Children 1-3 yr	20-80 ug	
4-6 yr	30-120 ug	
7-10 yr	50-200 ug	
11+ yr	50-200 ug	
> Adults	50-200 ug	

TABLE 1 - Continued

<u>Critical Levels of Exposure</u>	<u>Concentration/level</u>	<u>Reference</u>
Septal ulceration after 2 weeks and perforation after 2 months in workers exposed to zinc chromate	1000 ug/m ³	Langard and Norseth, 1979
No ulceration or perforations in workers after 18 months exposure to zinc chromate	20-100 ug/m ³	Langard and Norseth, 1979
Perforation in workers exposed to chromic acid mist	180-1400 ug/m ³	Kleinfeld and Rosso, 1965
Lethal dose of Cr+6 compounds by ingestion in humans	1.5-16 g	Langard, 1980
No adverse effects in cats exposed to trivalent Cr salts 1 hr daily/4 months	80,000-115,000 ug/m ³	Akatsuka and Fairhall, 1934
No adverse effects in dogs given Cr+6 in drinking water for 4 years	25 ppm	Arwar et al., 1961
Minimal lethal dose (i.v.) for sodium chromate in dogs	75,000 ug	NAS, 1974
Concentration associated with growth depression and liver and kidney damage in laboratory animals	50 ppm	MacKenzie et 1958

TABLE 2
 CARCINOGENICITY OF CHROMIUM COMPOUNDS IN EXPERIMENTAL ANIMALS
 INHALATION EXPOSURE

<u>COMPOUND</u>	<u>ANIMAL</u>	<u>EXPOSURE /DOSE</u>	<u>EFFECTS</u>	<u>REFERENCE</u>
Chromium containing dust CrO ₃ (+6) Cr ₂ O ₃ (+3) K ₂ Cr ₂ O ₇ (+6)	Mice	0.5-1 mg/m ³ 4h/d, 5d/wk 16-58 wk (11.5-83.5 mg/kg Cr)	No increase in lung tumor incidence	Baetjer et al. (1959)
	Rats	1-1.5 mg/m ³ 4h/d, 5d/wk > 70 wks (54.6-81.9 mg/kg Cr)	Increased incidence of lymphosarcomas involving lungs 3/100 rats	
Chromium containing dust CrO ₃ (+6) Cr ₂ O ₃ (+3) K ₂ Cr ₂ O ₇ (+6)	Rats	1-1.5 mg/m ³ 4h/d, 5d/wk for life (81.1-19.2 mg/kg Cr)	No increase in lung tumor incidence	Steffee and Baetjer (1965)
Chromium containing dust/mist CrO ₃ (+6) Cr ₂ O ₃ (+3) K ₂ Cr ₂ O ₇ (+6) Na ₂ CrO ₄ (+6)	Rabbits Guinea pigs	1.5-2 mg/m ³ 4-5h/d, 4d/wk Rabbits = 11.5-19.2 mg/kg Cr (50 mos) Guinea pigs = 50.9-84.9 mg/kg Cr (life)	No increase in lung tumor incidence	Steffee and Baetjer (1965)
CaCrO ₄ dust (+6)	Mice	4.33 mg/m ³ 5h/d, 5d/wk for life (811 mg/kg Cr)	6/136 males 8/136 females developed lung tumors	Nettesheim et al. (1971)
Minute Volumes	Mice = 1.2 liters/minute x kilogram Rats = 0.65 liters/minute x kilogram Rabbits = 0.04 liters/minute x kilogram Guinea pigs = 0.34 liters/minute x kilogram			

TABLE 3
 CARCINOGENICITY OF CHROMIUM COMPOUNDS IN EXPERIMENTAL ANIMALS
 ORAL EXPOSURE

COMPOUND	ANIMAL	EXPOSURE	EFFECTS	REFERENCE
Chromium acetate (+3)	Mice	5 ppm in drinking water for lifetime	No increase in tumor incidence	Schroeder et al. (1964)
Chromium acetate (+3)	Rats	5 ppm in drinking water for lifetime	No increase in tumor incidence	Schroeder et al. (1965)
Cr ₂ O ₃ (+3)	Rats	1,2, or 5% in diet 5 days/week 2 years	No increase in tumor incidence	Ivankovic and Preussman (1975)

* No studies could be found that tested chromium (+6) compounds

TABLE 4
TOXIC EFFECTS OF CHROMIUM COMPOUNDS IN EXPERIMENTAL ANIMALS
INHALATION EXPOSURE

<u>COMPOUND</u>	<u>ANIMAL</u>	<u>EXPOSURE</u>	<u>EFFECTS</u>	<u>REFERENCE</u>
CrO3 (+6)	Rabbits Guinea pigs Rats Mice	3-4 mg/m ³ 5h/d, 4d/wk for life Rabbits = 17.5 mg/kg Guinea pigs = 148.5 mg/kg Rats = 283.9 mg/kg Mice = 524.2 mg/kg	15% of rabbits & rats had granulomata Guinea pigs had alveolar & interstitial inflammation	Steffee & Baetjer (1965)
CaCrO4 (+6)	Mice	13 mg/m ³ 5h/d, 5d/wk lifespan (2434 mg/kg)	Depressed weight gain, lung effects, spleen & liver atrophy, stomach & intestinal ulceration	Nettesheim et al. (1971)
Minute Volumes	Mice = 1.2 liters/minute x kilogram Rats = 0.65 liters/minute x kilogram Rabbits = 0.04 liters/minute x kilogram Guinea pigs = 0.34 liters/minute x kilogram			

* No studies could be found that tested chromium (+3) compounds

TABLE 5
 TOXIC EFFECTS OF CHROMIUM COMPOUNDS IN EXPERIMENTAL ANIMALS
 ORAL EXPOSURE

<u>COMPOUND</u>	<u>ANIMAL</u>	<u>EXPOSURE</u>	<u>EFFECTS</u>	<u>REFERENCE</u>
K ₂ CrO ₄ (+6)	Rats	0.125-1% in diet	Rough, dirty coats, subnormal young, diarrhea, sterility	Gross and Heller (1946)
ZnCrO ₄ (+6)	Rats	0.125-1% in diet	Subnormal appearance, rough, dirty coats, sterility	
Cr ₂ O ₃ (+3)	Rats	2 or 5% in diet 90 days	Spleen & liver weight depression	Ivankovic & Preussman (1975)
		2 years	No treatment related effects

SAMPLING PROCEDURES

A standard test method for determining chromium emissions from stationary sources has not as yet been written by either EPA or the State of California. Both agencies have, however, sampled sources for chromium emissions based on modifying EPA Method 5 techniques. Contacts were made with the two agencies (Mr. Joe Noll of EPA, and Mr. Dean Simeroth of the State of California Air Resources Board) to discuss the sampling methods employed. The sampling method used in the present study used suggestions of the two agencies in addition to incorporating the experiences of CFT in analyzing samples for chromium. The method used in collecting the samples was basically EPA Method 5 with several modifications. The probe liner was glass to avoid any contamination from metal liners. Filter material was Teflon, manufactured by Membrana Inc. to avoid possible blank levels of chromium in other filter media. The 1.0 μm pore size filters exceed the performance criteria for filters specified in EPA Method 5. A nylon brush with Teflon tubing rod was used to clean the probe after each test. Probe washes were made using pH 2 sulfuric acid, since laboratory testing at CFT has shown this to preserve the oxidation state of chrome-containing particulate. 100-ml of distilled water was used in each of the first two impingers instead of the 200-ml amount specified in Method 5. This was done to improve the sensitivity of measuring small amounts of Cr in these solutions.

Except for the modifications noted above, EPA Method 5 procedures were followed in isokinetically sampling the sources. EPA Method 1 (as modified in Federal Register, V.48, no 191, p. 45034, 9/30/83) was followed to locate traverse points. Fyrite test kits were used in the O_2 and CO_2 determinations.

ANALYTICAL PROCEDURE

Samples collected in each test were recovered from the sample train and placed into four containers: probe and nozzle rinse, filter, first impinger catch, and second impinger catch. Each of the four fractions were analyzed separately. All impinger samples were analyzed for Cr^{+3} and Cr^{+6} content, while solids were analyzed for pH 2 sulfuric acid soluble Cr^{+3} and Cr^{+6} , and pH 2 sulfuric acid insoluble Cr^{+3} . The analytical methodology was a colorimetric diphenylcarbazide procedure and is found in Appendix A.

TEST RESULTS

Source conditions for each of the four stacks tested are given on Table I. Analytical results for the samples are shown on Table II. Chemical analysis of the impinger samples are not shown since all samples showed less than quantifiable levels of chromium (less than 0.00001 mg Cr^{+3} or Cr^{+6} per ml of impinger solution). Cr^{+6} in particulate samples was also not found at quantitation levels (less than 0.005 mg Cr^{+6} per filter, and less than 0.001 mg Cr^{+6} per 100-ml probe and nozzle rinse). Table III shows calculated grain loadings and mass loadings

J. G. Shepherd from R. J. Schlager
November 21, 1984

for the chromium emissions for the four sources. Samples identified as "insoluble" Cr on the Tables result from the way the particulate samples were prepared during analysis. In the analytical workup, Cr^{+6} and soluble Cr^{+3} were extracted from the particulate matter using dilute sulfuric acid (pH 2). The extract was analyzed for Cr^{+3} and Cr^{+6} content, and the residual particulate matter underwent additional analysis for insoluble Cr^{+3} determination. The "insoluble" values listed in the Tables are therefore the Cr^{+3} content of the particulate matter after dilute acid extraction to remove Cr^{+6} and soluble Cr^{+3} . Results of the chemical analysis of the field blank samples are shown in Table IV. Process data for the sources tested are given in Table V.

Sample data sheets and calculations are given in Appendix B. Calibration data for the EPA Method 5 meter case and pitot tube is given in Appendix C.

RJS:dn

SUMMARY

Four sources were tested at the Moss Landing facility for chromium air emissions. Chemical analysis of the samples show that no Cr^{+6} was detected in any sample. Cr^{+3} emissions were quantified for the Magnesia Plant Kiln 5, Brick Plant Kiln 2, and Brick Plant chrome drier. No detectable amounts of chromium were being emitted from Kiln 2 at the Magnesia Plant.

* * * * *

INTRODUCTION

Recent interest in toxic air pollutants at the State and local levels prompted a chromium emissions survey at Kaiser Aluminum & Chemical Corporations (KACC) Moss Landing Magnesia and Brick Plant. Four sources were identified for testing at the Moss Landing facility - kilns #2 and #5 at the Magnesia Plant, and tunnel kiln #2 and the "chrome drier" at the Brick Plant. The sources were tested on September 12, 13, 17, and 19, 1984. Each source was tested twice.

Regulatory agency visitors during portions of the testing were Mr. Kenneth A. Kitts and Mr. Bob Nishimura of the Monterey Bay Unified Air Pollution Control District, and Mr. Cliff Popejoy of the State of California Air Resources Board.

KACC's Center for Technology (CFT) and the Moss Landing Plant Technical Department performed the source testing, and the CFT Analytical Department provided sample analysis.

DISCLAIMER

This report was prepared by Battelle Columbus Laboratories, Columbus, Ohio. The statements contained herein are based upon general information available from a random examination of the refractories industry, certain testing of raw materials and products, and from other data sources. Neither The Refractories Institute, any member of The Refractories Institute, Battelle Columbus Laboratories, nor any person acting on behalf of any of them assume any liability with respect to the use of or for possible or actual damage resulting from the use of any information disclosed in this report.

All Rights Reserved. No part of this publication may be reproduced, stored in a retrieval system, or transmitted in any form or by any means: electronic, electrostatic, magnetic tape, mechanical, photocopying, recording, or otherwise, without permission from The Refractories Institute.

EXECUTIVE SUMMARY

The Refractories Institute commissioned Battelle Columbus Laboratories in the summer of 1981 to conduct an independent investigation to determine the effects of exposure to chromium compounds on human health and the environment. Battelle's study included a critical review of selected publications relating to chromium toxicity, a comprehensive survey of all 30 refractory plant locations in the United States, site visits to a representative group of manufacturing plants, and an analytical assessment to determine if trivalent chromium compounds used in manufacturing refractories were converted to hexavalent materials during the manufacturing process. The key findings are summarized below:

- (1) The principal forms of chromium used in making refractory brick do not appear to be linked with cancer. This group of materials, identified as trivalent chromium compounds from their chemical structures, have been used for decades to strengthen the heat resistance of furnace brick produced for extremely high temperature applications. The chromium content of these chrome-bearing refractories ranges from 30 to 90 percent of their total volume. The conclusion that exposure to trivalent chrome compounds does not cause cancer is supported by negative findings drawn from a variety of sources. These include in vivo and in vitro bioassays, laboratory studies into the effects of trivalent chromium on animals, and epidemiologic studies on human exposures.
- (2) A second type of chromium compound, chromic acid, is used in limited quantities for specific products at several refractory-making plants. It is also known as hexavalent chromium, and it is sometimes used as an additive by the refractories industry. Less than 550 of the 4,300 refractory workers in chrome-using facilities are potentially exposed to hexavalent compounds (325 of these exposed to trivalent and hexavalent, and 225 more to hexavalent alone). Hexavalent compounds have been consistently linked to an increased risk of lung cancer in exposed workers.

Additional support for this relationship has been provided by similar findings in laboratory animal experiments.

- (3) Active programs of occupational health have been established in most of the plants surveyed. Their concerns vary, but typically include: instruction in special work safety practices, the use of personal protective equipment to limit exposure to particulates, monitoring of chromium concentrations in the workplace, and installation of equipment to control dust levels in their plants. In addition, most plants require pre-employment physical exams as periodic medical check-ups.
- (4) Those refractories plants using chrome are usually well within OSHA's exposure limits for chromium compounds, according to monitoring data retrieved during site visits. These limits, which concern dust levels, are based on total chromium compounds present, but do distinguish between hexavalent and total chrome content. Of the 4,300 workers employed at the plants using chrome, no more than 1,725 are potentially exposed to trivalent compounds, fewer than 325 work with trivalent and hexavalent compounds, and less than 225 work exclusively with hexavalent compounds. In those plants where employees do work with hexavalent chrome, adequate exposure control measures appear to be in place.
- (5) Trivalent chromium is not transformed into significant quantities of hexavalent chrome during the manufacture of chrome-bearing refractory products. These refractory products, when they are shipped from the plant, usually contain trivalent chrome only. This conclusion, which confirms a long-standing impression among industry mineralogists, was substantiated by analytical laboratory studies using both raw materials and finished products from various plants.
- (6) The analyses of raw materials and finished refractory products revealed that the trivalent chromium raw materials, such as chromite, are not subjected to conditions which favor the formation of hexavalent chrome compounds during the production of refractories.

UNITED STATES ENVIRONMENTAL PROTECTION AGENCY
Office of Air Quality Planning and Standards
Research Triangle Park, North Carolina 27711

DEC 1 2 1984

Dr. Robert Drake
2721 Oak Valley Drive
Vienna, Virginia 22180

Dear Dr. Drake:

As you may know, the United States Environmental Protection Agency (EPA) is considering adding chromium to the list of hazardous air pollutants under Section 112 of the Clean Air Act, as amended, August 1977. A preliminary assessment has identified 11 categories of stationary sources as potential emitters of significant quantities of chromium to the atmosphere.

In addition to the previously identified 11 source categories, EPA is attempting to gather information on other sources of chromium emissions to determine if they may require further study as separate source categories. Included among these other sources are glass melting furnaces.

Because there are limited data and available information, especially with respect to the quantities and forms of chromium actually emitted, EPA has undertaken a program to develop additional background information on each source category. A major element of the program consists of locating and visiting a number of representative plants within each source category. From these visits, one or more plants may be selected as candidates for emission testing. The tests will be performed to quantify the amount and form (trivalent or hexavalent) of chromium discharged from chromium emitting facilities and air pollution control devices.

As we have discussed previously on the telephone, I have contacted the State of California Air Resources Board and requested available information on the use of chromium additives in Gallo Glass Company's glass melting furnaces in Modesto, California. I am enclosing a copy of that request in this letter for your information, along with a copy of the questionnaire that was sent to the State detailing the type of information we are interested in obtaining.

Any similar information of this type which the members of the Glass Packaging Institute may be able to provide to EPA would greatly help in determining the need to include glass melting furnaces as a separate source category in this study.

If you have any questions regarding this request, please contact me at (919) 541-5601.

Sincerely,

Peter Schindler

DISC: SCHINDLER ST
 11/17/84 III

Mr. Al Jenkins
 State of California Air Resources Board
 Post Office Box 2815
 Sacramento, California 95812

Dear Mr. Jenkins:

I would like to thank you for providing the emission testing reports and related information on the glass melting furnaces at the Gallo Glass Company in Modesto, California, as requested by Mr. Ron Myers in October. After reviewing the contents of the test reports, we have determined that there is need for some of the information that has been omitted from the test reports due to Gallo's proprietary concerns.

This letter is to request a copy of Table 1 on page 3 of Test Report No. C-84-016, "Emissions from Glass Melting Furnaces at Gallo Glass Company," dated August 1984, which contains process weight rates and other operating conditions for the furnaces. Enclosure 1 details a further request for information which may be available on all five glass melting furnaces at Gallo in addition to that data provided in Table 1. This information would help greatly in EPA's investigation of this source category for chromium emissions.

Enclosure 2 summarizes Agency and Emission Standards and Engineering Division policies and procedures for handling privileged information and describes EPA contractor commitments and procedures for use of confidential materials. EPA has contracted with Midwest Research Institute (MRI) (Contract No. 68-G2-3317) to obtain information pertinent to stationary categories which emit chromium. Thus, MRI has been designated by EPA as an authorized representative of the Agency. It is EPA's policy that compliance by an authorized representative with the requirements detailed in Enclosure 2 provides sufficient protection for the rights of submitters of privileged information.

Your efforts to provide EPA with this requested information at your earliest convenience would be greatly appreciated. If you have any questions regarding this request, please contact Mr. Peter Schindler at (919) 541-5501.

Sincerely,

Stanley T. Cuffe, Chief
 Industrial Studies Branch

ENCLOSURE 1

Please provide all of the information which may be available concerning these topics:

- ° Average feed rate and average product pull rate at each furnace during a melt cycle.
- ° Feed rate of $\text{Na}_2\text{Cr}_2\text{O}_7$ or other chromium-containing additive (lb/ton of virgin feed).
- ° Cullet ratio-percent recycled from product.
- ° Percent chromium in finished product.
- ° Individual furnace stack parameters
 - diameter
 - temperature
 - gas flow rate
 - height
 - height of tallest building within one stack height
- ° Any other emission test results on chromium from glass furnaces at Gallo or other plants.

AIR RESOURCES BOARD

2 Q STREET
P.O. BOX 2815
SACRAMENTO, CA 95812

June 18, 1985

Ms. B. J. Kirwan
McClintock, Kirwan, Benshoof,
Rochefort, and Weston
611 West Sixth Street, Suite 2100
Los Angeles, CA 90017

Dear Ms. Kirwan:

Comments on Draft Chromium Report

Thank you for the comments and suggestions of the Ad Hoc Environmental Group of the glass industry on the Draft Chromium Report. We have referred their comments on Part-B to the Department of Health Services (DHS) for response. Their comments, the DHS response, and this letter will be included in Part C of the Report to the Scientific Review Panel on Chromium. You will received a copy of that report. I am responding to their comments in the same sequence in which they appear in your letter.

Page 4, paragraph 2: Several people commented, as you did, that estimation of excess cancer burden based on the assumption that all ambient chromium is hexavalent is confusing or inappropriate. Consequently, to reduce the possibility of confusion, we have, in revising the report: 1. removed the table entitled "Excess Cancer Burden . . ." (overview, page 9); 2. deleted discussions of excess cancer risk presented which are based on the assumption that all ambient chromium is hexavalent; and 3. provided an estimate of a range of excess cancer risk from ambient hexavalent chromium based on measured chromium(VI) concentrations.

Please note that the Department of Health Services has revised the upper-bound dose-response relationship, and that the ranges of excess cancer risk presented in the overview have been changed accordingly.

Page 5, paragraph 2 and 3: We understand your sensitivity to possible public perception that all chromium may be "toxic." We have endeavored throughout the draft report to maintain a distinction between chromium(VI) and other forms of chromium, whenever technical data allowed such a distinction to be made. In cases where a lack of adequate data on the form or state of chromium in a particular usage or emission precludes its classification as chromium(IV) or chromium(III), we have so indicated, and used the more general term "chromium" or "total chromium."

In the draft Report, we present the required estimates of usage and emissions of chromium (differentiated as to its oxidation state, wherever possible). Estimation of cancer risk due to chromium(VI) is based directly on measured ambient air concentrations of total and hexavalent chromium and subsequent exposure assessment. The fact that current limited knowledge of certain sources does not permit the classification of chromium emissions as hexavalent or otherwise, does not affect the estimation of cancer risk from measured ambient chromium exposure, nor does it "increase it... beyond the facts," as you state. In the Draft report, the emission estimates and the exposure assessment used to estimate excess cancer risk are independent.

We believe the information presented in the draft report on usage and emissions of chromium, and specifically on chromium(VI), is adequate along with the exposure assessment and DHS health effects information, to justify listing chromium(VI) as a toxic air contaminant. A major part of any control effort for chromium(VI) will be a refinement of the emissions inventory, including direct measurement of emissions to detect and measure mass emissions of chromium(VI) from various source types.

Page 6, paragraph 3: Thank you for the information that there are six green glass manufacturers in California. We will change our report to reflect this fact. Your statement that, "At this time, all green glass colorant used is iron chromate or trivalent chrome," is unclear. Typically, iron chromite, which contains chromium in the trivalent state, or hexavalent chromium, are used as green-glass colorants. If iron chromate is being used in California, we would appreciate further information on its usage, because ARB source tests indicate that processes using chromate colorants have a greater potential for hexavalent chromium emissions.

Page 7, paragraph 1: The data concerning chromium(VI) emissions from a large green glass manufacturer and cited in the

June 18, 1985

report are from a final ARB report (given as ref. I-19 in the Draft Chromium Report) which received public review and which was modified to address the comments received. Further testing of that large green glass manufacturer is scheduled because formulation changes have occurred which may affect chromium(VI) emissions. Based on information supplied by industry, the information gathered in April, 1984 on chromium(VI) emissions from that large green glass manufacturer may not represent current emissions; however, we believe that the 1984 test data are technically supportable, and are representative of emissions from the plant at the time of the tests.

Page 7, paragraph 2: The ARB's interest in potential chromium(VI) emissions from clear glass plants is supported by EPA or EPA-sponsored reports indicating that greater than trace levels of chromium(VI) had been measured in the emissions of clear glass plants; these were cited as references 20 and 21 of Section I of Part A of the Draft Report on Chromium.

Subsequent to the issuance of the draft chromium report, data became available on chromium (hexavalent and total) emissions from a clear glass plant in California. As you indicated, emissions of chromium(VI) were very low in this test. We will indicate this in the revised report. Any decisions on the source types to be evaluated for controls will be made during the control development phase. We expect additional data from ARB and industry emissions testing of glass plants will be available if we do proceed to a control development phase for hexavalent chromium.

Page 7, paragraph 3: The emissions listed in Table I-1 for refractory production were trivalent chromium. We have estimated maximum chromium(VI) emissions based on the detection limits of the source test performed for chromium(VI) at Kaiser plant, and will indicate in the Report that emissions of chromium(VI) are less than that amount.

Page 8, paragraph 2: Estimates of chromium(VI) emissions from glass manufacturing were not included in Table I-1 of the Draft Report because there is insufficient evidence available to make an accurate estimate of statewide emissions, not because the source category is believed to be insignificant. We have clarified this in the report.

We note that in the letter from Peter J. Schindler of the U.S. EPA to Mr. Robert Drake (dated December 12, 1984) which you attached to your comments as exhibit 6, Mr. Schindler states:

"In addition to the previously identified 11 source categories, EPA is attempting to gather information on other sources of chromium emissions to determine if they may require further study as separate source categories. Included among these other sources are glass melting furnaces."

We believe the omission of the glass industry in Table 3-6 of the "Health Assessment Document for Chromium" reflected a lack of information by EPA on emissions from the industry and is not an implicit statement that glass plants do not have the potential to emit chromium, or that these emissions are, or are not, significant.

Page 9, paragraph 2: An EPA sponsored test, cited as reference 20 in Part I, indicates that chromium was emitted from a green glass furnace in which chromium(VI) colorants were used; the oxidation state of the chromium was not specified. Because the information is not specific to chromium(VI), and because ARB testing of a California green glass plant using chromium(VI) colorants showed significant chromium(VI) emissions, reference to the EPA sponsored work in regard to this point has been removed from the report.

Page 9, 10 (conclusion): The best available emission data and usage information on chromium(VI) have been used in the report. Where data were insufficient to permit classification of chromium emissions as hexavalent, total chromium was reported, and deficiencies or uncertainties in the data identified in the report. Any control decisions will be made during a control development phase, if chromium(VI) is identified as a Toxic Air Contaminant by the Air Resources Board.

Again, thank you for your comments. You may contact Cliff Popejoy at (916) 323-8503 if you have further questions.

Sincerely,

William V. Loseutoff, Chief

COMMENTS ON ARB/DHS
DRAFT REPORTS ON CHROMIUM

Mr. William V. Loscutoff, Chief
Toxic Pollutants Branch
Air Resources Board
P.O. Box 2815
Sacramento, CA

Dear Sir:

Chevron has reviewed the draft reports on Chromium and we appreciate the opportunity to comment prior to submitting the reports to the Scientific Review Panel. The following summarizes our major observations on both "Part A - A Review of Chromium Uses, Emissions and Public Exposure" and "Part B - Health Effects of Chromium." More detailed comments prepared by our experts at Chevron Research Company and the Chevron Environmental Health Center are included as attachments.

PART A

The overly conservative assumptions made in the selection and handling of exposure data result in an estimated exposure level of hexavalent chromium that may be as much as a factor of six too high. When this overly conservative exposure estimate is coupled with the Department of Health Service's dose response data, the result is an estimated population risk that is also a factor of six too high (See items 1 and 2 on Attachment I).

PART B

The epidemiology studies used as a basis for the Department of Health Service's risk assessment may be adequate for a qualitative evaluation of health risk, but each of the studies cited has at least one major defect which seriously limits its use as a basis for quantitative risk assessment (See Attachment II). Therefore, we believe:

- 1) It is premature to produce statistical estimates of risk based on current data, and
- 2) Risk management decisions should not be made until sufficient data is available to make a quantitative risk assessment.

We hope these comments will be of value in revising your draft documents. If you have any questions, please contact Mark Nordhiem at (415) 894-6107.

Sincerely,

W.T. Danker/mwn

ATTACHMENT I

CHEVRON COMMENTS ON THE AIR RESOURCES BOARD DRAFT "PART A" REPORT ON CHROMIUM

1. The Air Resources Board Staff report recommends that only hexavalent chromium be listed as a Toxic Air Contaminant since there is insufficient evidence that trivalent chromium causes cancer. However, annual ambient concentration estimates used to predict excess cancer rates are based on measurements of total chromium. At the same time, the Part A report states that recent ambient data show hexavalent chromium represents up to one-third of the total chromium present in the air. Therefore, the estimated ambient concentrations of hexavalent chromium and the resulting predicted cancer rates are unrealistically high by at least a factor of three.
2. The ARB measured chromium in nine cities during 1982-1983. However their program did not cover a full year. For this reason, the annual ambient concentration estimates for chromium are based on 1977 monitoring data from EPA's National Aerometric Data Bank. These measurements were originally obtained from various public agencies, which probably used a variety of collection and analysis methods. For the three cities included in both data bases, average chromium levels measured by CARB are a factor of two lower. Therefore, using the EPA data results in predicted cancer rates that may be a factor of two high. When this effect is combined with the effects of item one above, the result is a cancer risk estimate that may be a factor of six too high.
3. The relative magnitude of hexavalent chromium emissions from various sources needs to be better defined before an effective control program can be devised. Cooling tower emissions illustrate this point. According to the draft report, they may be responsible for as little as 0.6% or as much as 20% of total chromium emissions from stationary sources. A more precise estimate is required to determine whether controls should be considered for this source category.

ATTACHMENT II

CHEVRON COMMENTS ON THE DEPARTMENT OF HEALTH SERVICES DRAFT "PART B" REPORT ON CHROMIUM

Following a review of the DHS/EPA risk assessment for chromium, we are concerned that the epidemiology studies cited by both the DHS and EPA are inadequate for the quantitative estimation of cancer risk associated with ambient airborne concentrations of chromium. Each of the studies selected has at least one characteristic (such as questionable quantitation and speciation of airborne chromium levels, concurrent exposure of the cohort to known carcinogens, and poor cohort definition) which seriously limits their utility for quantitative risk assessment. Most of these characteristics tend to overestimate the risk. The use of questionable data as the basis for a risk assessment can only result in estimates of dubious accuracy. For this reason, we believe it is both premature to perform rigorous mathematical estimates of risk based on the available data and misleading to present such estimates to risk managers as accurate. Our concerns for each of the studies cited are outlined below.

Pokrovskaya, et. al.:

1. In reviewing this study EPA concludes "although this study showed a significant increase of lung cancer mortality over the control group, the validity of the data is questionable because the study cohort is not clearly defined." Thus, it is inappropriate to use this data for a rigorous risk assessment.
2. In addition to chromium, the study's authors reported that workers were exposed to other potentially carcinogenic substances including benzo (a) pyrene and furnace gases. No attempts were made to account for these confounding factors.

Axelsson, et. al.:

1. The authors of this study concluded that there was no association between employment in the ferrochromium industry and risk of respiratory cancer. Thus this data is theoretically useful only in calculating an upper-bound estimate of potency.
2. Because of the confounding effects of smoking and exposure to asbestos (two of the four cases of respiratory cancer observed were diagnosed as mesotheliomas), no definite conclusions should be drawn from this study.

Langard, et. al.:

1. Ambiguity exists over the authors' classification of the observed cases of "lung cancer." This raises questions as to the authors' comparisons of observed and expected cases. If the observed number of "lung cancer" cases includes mesotheliomas, then the stated "lung cancer" risk due to chromium may instead be a partial reflection of the asbestos exposure believed to have also occurred in this cohort.

2. Measurements of airborne chromium levels were not taken until 1975, and may seriously underestimate the actual ambient levels to which most of the workers were exposed. EPA states that "These concentrations are used in our potency calculations, with the understanding that the potency so estimated can only be considered an upper-bound estimate" (emphasis added).
3. As in the Pokrovskaya study, these ferrochromium workers may have been exposed to two other carcinogens, asbestos and polycyclic aromatic hydrocarbons.

Mancuso:

1. In reviewing this study, the EPA concludes that the observed association between chromium exposure and lung cancer is "based on very small numbers, and thus the findings of a dose-response is probably questionable."
2. Two factors that may result in an overestimation of the risk association with exposure to chromium from the application of this study's results are:
 - a. The 1949 industrial hygiene data used in this study may underestimate the workers' exposure.
 - b. An implicit assumption was made that the smoking habits of chromate workers were similar to those of the general white male population.

Dear Mr. Danker:

Comments on Part A of the Draft Chromium Report

Thank you for your comments and suggestions on the Draft Chromium Report. The Department of Health Services will prepare responses to your comments on Part B. Those responses, this letter, and your comments will be included in Part C of the Report to the Scientific Review Panel. We will send you a copy of that report. Briefly, our response to your comments in Attachment I to your letter are as follows:

1. Several people commented, as you did, that the application of dose-response data for hexavalent chromium to total ambient chromium concentrations provides estimates of excess cancer risk which, because they represent worst case or upper bound estimates, are unrealistically high. We have revised the overview to include estimates of excess cancer risk which reflect current knowledge of ambient hexavalent chromium concentrations. The resulting risk estimates are approximately one-third the value of the upper-bound estimates.

Please note that the Department of Health Services has revised the upper-bound dose response relationship, and that the ranges of excess cancer risk have been changed accordingly.

The ARB is working to better characterize ambient levels of chromium(VI) in California. As more temporally and spatially specific data on chromium(VI) concentrations becomes available, it will be possible to make a better estimate of the health impact of ambient chromium(VI).

Mr. W. T. Danker

-2-

June 13, 1985

2. Ambient concentrations of total chromium measured by the ARB in 1982-83 are lower than those in the EPA National Aerometric Data Bank for 1977 because different sampling methods were used. The EPA data is from samples collected using high-volume samplers, which collect particulate matter less than 50 micrometers (um) in diameter; ARB data is from samples collected using dichotomous samplers, which collect particulate matter less than 10 um in diameter (inhalable particulate).

The difference between EPA and ARB data is indicative of a difference in sampling techniques which provide information on the particle size distribution of chromium particulate, rather than of differences in ambient chromium concentrations.

3. We agree that an improved emissions inventory will be an important part of any control program for hexavalent chromium. A decision on whether or not to require controls on specific source types will be made during the control measure development phase.

Again, thank you for your comments. If you have any questions, please contact Cliff Popejoy of my staff at (916) 323-8503.

Sincerely,

RE: March 1985 Draft
Report to the Scientific Review Panel on Chromium

Dear Mr. Loscutoff:

This letter is submitted to forward comments on the above-referenced draft Report to the Scientific Review Panel on Chromium. These comments should be considered as being additional to those previously submitted by our Mr. Ralph Temple.

If you have any questions on these comments, please let me know at (214) 922-2739 on the letterhead address.

Sincerely,

M. M. Skaggs, Jr.
Technical Manager, Environmental Affairs

MAY 16 1985

COMMENTS ON PART A, SECTION III.
AMBIENT CONCENTRATIONS IN THE COMMUNITY

1. "Non-Detectable" Data Handling: All ambient samples which contained non-detectable chromium levels were entered into the analysis as positive values. These data points were assumed to be equal to "one-half of the lowest non-zero concentration measured" (Page III-1). This assumption forces the data set minimums to be 4 ng/m³ of chromium. This method appears to have little merit or statistical support, particularly where the data is then fed into a linear carcinogenicity model.

2. Chromium Valence State: This report bases its cancer incidence assessment on the assumption that ambient chromium is entirely hexavalent in form. This assumption is invalid, particularly in light of the unreported S.C.A.B. data reported on Page III-8. This non-peer reviewed data is quoted as showing that only approximately one-third of the ambient chromium is hexavalent. Thus, the total chromium figures from Table III-1, III-2, III-3, III-4, III-5 and III-6 should be evaluated in this context.

3. Synergism of Assumptions-Cancer Risk: The two assumptions objected to above operated synergistically to bias the entire analysis. To see the problems with these paired assumptions, one should examine the application of these assumptions to the zero ambient chromium theoretical condition. In this case, while absolutely no chromium would be present, the model would be based on uniform assumed values of 4 ng/m³ (all hexavalent). Application of these assumed values to Figure A (Page 8) would result in an "estimated excess cancer burden" of 130 to 18,000 cases. Thus, despite an absence of environmental chromium in this hypothetical case, the model used would predict major public health impacts.

4. Monitoring Site Location: The monitoring sites at which the ambient chromium data were collected were not justified by modelling or other means as being appropriately located to be representative of the public exposure in their respective areas. Without such siting qualification, the assumptions of population exposure made on Page III-8 through III-19 are invalid. Impacts from intermittent local sources, which would normally disqualify air quality monitoring sites, were in fact used to explain away data variabilities. Thus, without a clearer examination of the monitoring site locations, nearby sources, and local meteorology, one should disallow much of the data as not being representative of the nearby populated areas.

5. Data Accuracy: Page III-19 states that "the accuracy of the chromium measurements is undocumented". Any data presented without adequate quality controls should be removed, as should any data not subjected to prior peer review.

Mr. M. M. Skaggs, Jr.
Technical Manager, Environmental Affairs
Diamond Shamrock Corporation
717 North Harwood Street
Dallas, TX 75201

Dear Mr. Skaggs:

Comments on Draft Chromium Report

Thank you for your comments on the Draft Chromium Report. Your comments and our responses will be included in Part C of the Report on Chromium to the Scientific Review Panel. We will send you a copy of that report. Our responses to your numbered comments are as follows:

1. Non-Detectable Data Handling

The replacement of zero values in the EPA National Aerometric Data Bank data used for the exposure assessment with a value one-half of the lowest reported non-zero concentration was done to provide a better estimate of average concentrations than would be the case if the zero values were either eliminated from consideration, included as zero, or included as being equal to the lowest non-zero concentration measured during the year. The percentage of observations at each site reported as zero ranged from 3 to 77. The overall average percentage of concentrations reported as zero was 27. Two-thirds of the sites (10 of 15) had 33 percent or fewer zero values, and one-third of the sites (5 of 15) had fewer than 10 percent zero values.

2. Chromium Valence State

Several people commented, as you did, that the application of dose-response data for hexavalent chromium to total ambient chromium concentrations provides estimates of excess cancer risk, which, because they represent worst case or

June 17, 1985

upper-bound estimates, are invalid. We have revised the overview to include estimates of excess cancer risk which reflect the current knowledge of ambient hexavalent chromium concentrations. The resulting risk estimates are approximately one-third the value of the upper-bound estimates.

Please note that the Department of Health Services has revised the upper-bound dose-response relationship, and that the ranges of excess cancer risk have been changed accordingly.

The data on hexavalent chromium concentrations in the South Coast Air Basin which were used to estimate risk from ambient chromium(VI) were based on ARB method 106, Procedure for the Sampling and Analysis of Atmospheric Hexavalent Chromium(VI). We have included a copy of Method 106 in Appendix D of Part A. A limited interlaboratory study of this method has shown agreement within 25 percent. Method development for chromium(VI) analysis is presently being done by the Inorganic Toxics Analytical Subcommittee of the Toxics Air Monitoring Technical Advisory Committee (TAMTAC) which is comprised of technical representatives of Federal, State, and local air quality and public health agencies.

3. Synergism of Assumption Cancer Risk

The two assumptions which you object to were discussed above; in summary, we believe the use of one-half the lowest non-zero concentration measured for observations reported as zero yields the best estimate of concentration possible using existing information. In addition, data on ambient hexavalent chromium concentrations were used to estimate a range of risk from hexavalent chromium. Because estimates of hexavalent chromium emissions indicate that hexavalent chromium is emitted to the atmosphere of California, the "hypothetical case" of "zero ambient chromium" is unlikely. Efforts are underway to better characterize ambient chromium(VI) concentrations at sites throughout the state. As additional data become available, we will be able to better assess the public health impact of ambient chromium(VI).

4. Monitoring Site Location

The monitoring sites at which the EPA NADB data were collected were established to provide data reflecting population-oriented chromium concentrations.^{1/}

Discussions of peak-to-mean ratios of TSP chromium and of di-chot fraction chromium were included in the report to provide an indication of the homogeneity of source areas.

June 17, 1985

Because chromium(VI) at the levels observed in ambient air is expected to have a chronic effect, the lifetime exposure or dose to the individual is used to estimate health impact. Therefore, intermittent sources of chromium(VI) are significant and should be considered in estimating population-oriented exposure. Based on these factors, we believe the data is representative of population exposure, and its use is appropriate.

5. Data Accuracy

While the absolute accuracy of the EPA database is not documented, certain procedures have been implemented to provide for reliable data. The chromium data were originally sampled and analyzed by a number of different agencies; these agencies presumably applied acceptable quality assurance practices during the collection and analysis phases. Additionally, after the data were received by EPA, they were subjected to several checks^{2/} to assure accuracy and completeness: edit checks, to determine whether the data met minimum completeness requirements; data validation, to determine whether the data reflect true or realistic situations based on guideline values, reasonable range checks, etc.; and certification, review of data after validation. We feel that the EPA data used to assess exposure was collected using adequate quality controls, and that review by various agencies represents sufficient peer review.

Thank you again for your comments. If you have any questions, please contact Cliff Popejoy, at (916) 323-8503.

Sincerely,

William V. Loscutoff, Chief
Toxic Pollutants Branch
Stationary Source Division

Mr. William V. Loscutoff, Chief
Toxics Pollutants Branch
Re: Chromium
California Air Resources
Board (ARB)
P.O. Box 2815
Sacramento, CA 95812

Dear Mr. Loscutoff:

Comments on Draft Chromium Risk and Exposure Assessment

PGandE supports the draft assessment's apparent conclusion that only hexavalent chromium could be considered for possible identification as a toxic air contaminant at this time. However, PGandE suggests that conclusion should be more clearly stated, and the rest of the report should be more consistent with that conclusion.

In August 1984, the Environmental Protection Agency (EPA) final chromium risk assessment concluded on page 2-11 that trivalent compounds have not been reported to be carcinogenic by any route of administration. In its Part B report, the Department of Health Services (DHS) concluded that there is inadequate data to confirm or refute the carcinogenic potential of trivalent chromium. Nevertheless, the Part B summary concludes "The DHS recommends that the ARB take the increased carcinogenic risk from exposure to chromium₃ (emphasis added) as falling in the range of 3.0×10^{-1} to 9.3×10^{-1} per $\mu\text{g}/\text{m}^3$." That recommendation is the most important part of this entire assessment. PGandE suggests that it be clarified that the DHS is not recommending applying hexavalent chromium based risk estimates to all chromium compounds.

The EPA assessment also concluded that hexavalent chromium compounds have not induced lung tumors by inhalation (page 2-11). We understand the health protective concerns which have caused the DHS to nevertheless recommend that hexavalent chromium be regulated as if we were certain it

MAY 13 1985

May 13, 1985

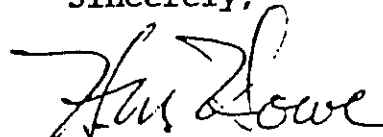

created the upper bound health risks implied by some epidemiological studies. But the overview table entitled "Estimated Excess Cancer Burden to Selected California Populations" fails to acknowledge that the actual risk may be zero. This is particularly misleading since one of the "health conservative" estimates is labeled as "low." It should be clarified that this is the lower upper bound, not an absolute lower bound, estimate. A footnote should also be added acknowledging the uncertainties of these health protective risk extrapolations and the possibility that the risk might actually be zero.

PGandE is disappointed that the "best" burden estimate is based upon an assumption that all ambient chromium is hexavalent when the only data cited indicates that only one-third of the ambient may be hexavalent. The ARB should either delay finalizing the report until it has better data or should base its "best" estimate on the best data available. In any event, it is clearly inappropriate to apply the 100% hexavalent assumption to any "low" estimate.

Table I-1 in Part A lists sources of chromium emissions. PGandE suggests that the ARB expand that table to include HIGH, BEST, and LOW estimates of the fraction of total chromium emissions from each source believed to be hexavalent. Absent data to the contrary, PGandE suggests that the ARB should rely upon the conclusion, implied on page 2-3 of the final EPA assessment, that oil combustion sources are unlikely to be sources of hexavalent chromium.

PGandE appreciates this opportunity to comment on the draft chromium assessments. Please call Mr. J. T. Holcombe at (415) 972-6910 if you have any questions regarding these comments.

Sincerely,

EPA-600/8-83-014F

2. SUMMARY AND CONCLUSIONS

2.1. INTRODUCTION

Trivalent Chromium (Cr III) is considered an essential micro-nutrient at relatively low levels, largely because chromium deficiency results in a buildup of glucose in the blood. At much higher levels, certain hexavalent chromium (CrVI) compounds are known to be carcinogens. Thus, chromium is unique among the metallic elements, given its paradoxical roles in both nutrition and carcinogenesis. The seemingly contradictory information on the effects of chromium is being clarified through increasing understanding of the role of the differing oxidation states and types of chromium compounds, which apparently determine the relative risks and benefits to human health of chromium in its various forms.

In the ambient environment, however, most of the monitoring information has provided only total elemental chromium levels. Outside of occupational settings, only limited information exists on the types of chromium compounds to which the public is exposed, although the trivalent form is known to be predominant. The assessment which follows focuses on several key areas which bear on the kind and extent of effects associated with chromium compounds: sources and concentrations of important chromium compounds (particularly Cr(III) and Cr(VI)); measurement methods; pharmacokinetics and essentiality; toxic effects in man and animals; and carcinogenic risks.

2.2. FORMS, SOURCES AND CONCENTRATIONS OF CHROMIUM

Chromium is a metallic element which occurs in nature primarily as the mineral chromite; elemental chromium does not occur naturally. Chromium exists

in four oxidation states, but only two of them, Cr(III) and Cr(VI), appear to be important, owing to their predominance and stability in the ambient environment. All forms are influenced greatly by pH, which affects the solubility and subsequent reactivity of chromium ions. Trivalent chromium is chemically basic, while hexavalent chromium is acidic.

Trivalent chromium is the most stable oxidation state, and the most important chemically. Its foremost characteristics are its ubiquitousness in the environment as part of the earth's crust, and its tendency to form kinetically inert hexacoordinate complexes. It reacts with aqueous hydroxides to form insoluble chromium hydroxide. Hexavalent chromium is the second most stable state, but the most important toxicologically. It occurs rarely in nature, apart from man's intervention, because it is readily reduced to Cr(III) in the presence of organic matter. It is quite soluble, existing in solution as a complex anion. However, in certain soils and natural waters, it can remain unchanged for protracted periods of time.

Chromite ore is not mined in the United States, but Cr(VI) chemicals are produced from imported ores, amounting to 21% of total U.S. chromium consumption. Metallurgical processes constitute approximately 60%, and refractory uses about 18%. Little direct information exists on the speciation of chromium compounds in the environment, because of the limitations of existing measurement methods (as described below). Accordingly, knowledge of chromium chemistry and its sources must be relied on in estimating the relative ambient contribution of different species. Direct sources include chemical and refractory plants; indirect sources include fossil fuel combustion, waste incineration and cement plant emissions.

Some source categories are likely to emit both trivalent and hexavalent forms of chromium. These are steel, refractory, chemicals manufacturing, as well

as sewage sludge and municipal incineration. Cooling towers and chrome plating facilities emit hexavalent chromium, and chromium ore refining, ferro-chromium production, cement production, and coal and oil combustion are likely to be sources of trivalent chromium. Maximum annual average ambient (total) chromium levels within 20 kilometers of these sources range from approximately 0.01-13.50 $\mu\text{g}/\text{m}^3$.

Background ambient air concentrations of total chromium have ranged from as low as 0.005 ng/m^3 (at the South Pole) to 1.1 ng/m^3 in other remote areas of the world. In the United States, recent monitoring of the ambient air in many urban and non-urban areas has shown total chromium concentrations averaging in the range of approximately 0.005-0.157 $\mu\text{g}/\text{m}^3$. The maximum 24-hour average concentration found for any one site was 0.684 $\mu\text{g}/\text{m}^3$ in the Baltimore, MD area. Because Cr(III) is highly stable and Cr(VI) reacts over time to form Cr(III), it is assumed that most chromium in ambient air occurs in the trivalent state. Monitoring of both the species and oxidation states of chromium in the ambient air should be a priority for future research.

The chromium concentration in U.S. waters varies with the type of surrounding industrial sources and the type of underlying soils. An analysis of approximately 4,000 tap water samples in representative U.S. cities showed chromium concentrations ranging from 0.4 to 8 ppb. Chromium levels in soil vary with soil origin and degree of contamination from anthropogenic sources. Tests on domestic soil have shown chromium concentrations ranging from an average of 14-70 ppm. Because the amount of chromium in food and food plants is relatively low, and because chromium does not appear to accumulate in mammalian systems, bioaccumulation in the soil-plant-animal system does not appear to be a significant exposure source.

2.3. MEASUREMENT METHODS

One of the main problems in assessing the effects of chromium on human health is the lack of adequate methods to measure the types and amounts of chromium compounds. Prior to 1978, urinary chromium levels fell within the range of 2 to 20 $\mu\text{g}/\text{l}$. In 1971, radio-tracer experiments indicated that approximately 0.5-1% of the chromium was absorbed through the digestive system. Accordingly, chromium excretion of 10 $\mu\text{g}/\text{day}$ would correlate with a chromium intake of 1-2 mg/day. However, few diets contain more than 100 $\mu\text{g}/\text{day}$ chromium; this anomaly was resolved by showing that the background collection capabilities of the analytical methods used to measure chromium (atomic absorption) were inadequate for chromium determinations.

Several methods are available for measuring elemental chromium in both environmental and biological samples. These include atomic absorption spectroscopy, instrumental neutron activation analysis, X-ray fluorescence, and particle-induced X-ray emissions (PIXE). While these methods are sensitive to the ppb level, problems in sample collection, preparation and interferences are shared by all. In biological samples, neutron activation analysis data tend to be lower than atomic absorption and X-ray fluorescence data. In environmental samples, neutron activation analysis data are higher. Generally, a comparison of the results indicates that modified atomic absorption spectroscopy provides relatively reliable analyses. Another problem in chromium determination is the lack of adequate reference materials. Ideally, reference materials should match the samples to be analyzed with respect to chromium levels and each reference composition. Because the materials are not yet standardized, inter-laboratory comparisons are difficult.

Techniques for monitoring hexavalent chromium are also subject to considerable error. For example, although the OSHA colorimetric method is the

most commonly used analytical tool, particularly in occupational settings, low sample recoveries have been reported in chromium levels of less than 10 μg .

2.4. PHARMACOKINETICS AND ESSENTIALITY

2.4.1. Absorption, Transport and Excretion. An understanding of the role of chromium as an essential nutrient and causative agent in toxicity and carcinogenicity requires knowledge of the rates of absorption, mechanisms of absorption, transport and organ distribution of the various chromium-containing compounds. There are three primary routes of entry for chromium into the human body. For most people, the gastro-intestinal (GI) tract is the primary route of uptake, while in occupational exposures the airways and skin are the most important routes of uptake. Rates of uptake in the GI tract depend on a number of different factors, such as the valence state of chromium in the compound, the water solubility of the compound and the passage of time through the tract. Uptake in the airways is also influenced by the particle size distribution of the inhaled aerosols, and on factors which govern the clearance time of the lung.

Limited work on humans has been carried out on the relationship between exposure to trivalent chromium compounds and lung uptake and urinary excretion of chromium. In one study on workers exposed to chromium lignosulfonate, it was demonstrated that while chromium in the chromium lignin was present in the trivalent state, it acted pharmacokinetically like water soluble Cr(VI) compounds. An average of 14 $\mu\text{g}/\ell$ of urine was excreted, at an atmospheric chromium lignin concentration of 50 $\mu\text{g}/\text{m}^3$. One to two percent of the inhaled chromium was excreted in the urine.

For Cr(VI), the urinary chromium concentrations corresponding to an airborne concentration of 50 $\mu\text{g}/\text{m}^3$ Cr(VI) were 40 $\mu\text{g}/\ell$ in one study, and 10 to 20

µg/l in another. It was noted that chromium-bearing particles stay longer in the airways in smokers than in non-smokers.

The established normal levels of chromium in whole blood and in serum have declined with time, reflecting the changes and improvements in analytical methods. In the airways and in the GI tract, soluble Cr(VI) compounds are apparently taken up by epithelial cells by simple diffusion through the plasma membrane. After entry, Cr(VI) reduction occurs from the action of enzymatically mobilized electrons, which are available from GSH, NADPH, and NADH. The reducing capacity inside the cell is limited, so that Cr(VI) and Cr(III) exist simultaneously inside the cytoplasm; Cr(VI) is then released from the cell by simple diffusion into the blood stream and taken up into blood cells. In spite of the refined methods of analysis available, a reliable range of normal blood chromium concentrations cannot be given with confidence. When using modern methods for analysis, the whole blood concentration may be suggested to be within the range of 0.5 to 3 ppb, while the serum level is probably below 0.2 ppb.

The chromium concentration in human tissues has been shown to decrease with increasing age. In contrast to this, chromium concentrations in the lung have been shown to increase with age. This increase in chromium content in the lungs may be due to deposition and retention of insoluble chromium-containing particles from the inhaled environmental air, as well as from tobacco smoke.

2.4.2. Essentiality of Chromium. Animal studies have demonstrated that chromium-deficient rodents gain less weight and have a shorter life-span than animals maintained on a diet containing adequate chromium values. Chromium deficiency results in glucose intolerance in rats. This intolerance can be reduced with dietary treatment with Cr(III). In humans, symptoms of chromium deficiency consist of glucose intolerance, weight loss and confusion. Those

prone to chromium deficiency include the elderly, diabetics, pregnant women, malnourished children, offspring or siblings of diabetics and persons with early coronary heart disease. Although the exact level of chromium needed for good health is not known, the average American intake of 50 to 200 $\mu\text{g}/\text{day}$ is considered adequate because at such levels symptoms associated with chromium deficiency are not observed. It should be noted that there is a considerable difference between the low levels of intake that are associated with nutritional deficiency and the high levels of exposure which are associated with toxic effects.

2.5. EFFECTS OF CHROMIUM ON BIOLOGICAL SYSTEMS AND HEALTH

2.5.1. Toxic Effects in Man and Animals. The effects of both Cr(III) and Cr(VI) have been studied in man and animals. Both long-term and short-term exposure conditions have been investigated, but most of the long-term exposures have focused on carcinogenic effects (discussed in Section 2.5.2. below).

The relative chemical inactivity of Cr(III) compared with Cr(VI) correlates with various acute toxicity studies on chromium salts. Oral LD_{50} (dose lethal to 50% of recipients) levels in rats have been reported to range from 135 mg/kg to 11,260 mg/kg for Cr(III). As seen in the previous section on pharmacokinetics, the relatively high amounts of Cr(III) which are required to cause death arise from the relative insolubility and poor intestinal absorption of most Cr(III) compounds. Unlike the trivalent compounds, those of Cr(VI) tend to cross biological membranes fairly easily, and are somewhat more readily absorbed through the gut or through the skin. The strong oxidizing powers of Cr(VI) compounds explain much of their irritating and toxic properties.

Exposure to Cr(VI) has been associated primarily with renal damage. For humans no quantitative evidence of acute toxicity through oral ingestion has been

reported. In various animal species, single injections of 2 mg/kg caused cellular and structural damage in the kidneys.

The effects of chromium on the skin were recognized over 150 years ago. Many chromium compounds can damage the skin, but metallic chromium or chromium alloys are chemically inert and are not harmful. The effects of chromium compounds on the skin are caused primarily by direct contact. Most of the effects have occurred in occupational settings, and, as expected, with more men than women reporting effects. Cr(VI) derivatives can cause ulcers of the hands and accompanying perforations of the nasal septum. Allergic contact dermatitis may arise from exposure to either trivalent or hexavalent chromium, although hexavalent chromium is responsible for most of the reported cases. Cr(VI) penetrates undamaged skin, and subsequently reduces to Cr(III) which combines with proteins or other skin components to form a whole skin allergin.

Effects on the upper respiratory tract have been observed in workers in chromium-related industries. The major effects of chromium on this system include ulceration of the nasal septum, with subsequent perforation, and chronic rhinitis and pharyngitis. Early studies indicated that approximately one-half to four-fifths of the workers in chromate plants had perforated nasal septa, at levels of exposure that approached 1 mg/m^3 . Subsequent work indicated that chromic acid levels exceeding 0.1 mg/m^3 also caused perforated septums in some workers.

Limited work has been reported on reproductive effects of chromium. Cr(VI) and Cr(III) have been found to cross the placental barrier in animals (hamsters and mice) and enter the fetus during mid to late gestation. Fetal uptake of Cr(VI), however, was much greater than that of Cr(III). Developmental effects attributed to both Cr(VI) and Cr(III) differed between hamsters and mice, and included such external abnormalities as cleft palate and skeletal defects, and

(in one study of a Cr(III) compound) neural tube defects. One researcher concluded that Cr(VI) occurred at sufficiently high fetal concentrations to cause direct effects on embryonic structures, but also questioned whether all of the teratogenicity and fetal toxicity associated with exposure to Cr(III) might be attributed to extra-embryonic effects, for example, those on placental tissues.

2.5.2. Genotoxicity, Carcinogenicity and Assessment of Risk.

2.5.2.1. GENOTOXICITY -- In recent years, much evidence has accumulated to show that compounds of chromium possess the ability to cause transformations and mutations, as evaluated in a wide variety of in vitro assays such as the reverse and forward mutation, gene conversion, and DNA modification tests. Genotoxic effects have been demonstrated primarily for chromium compounds containing the Cr(VI) species, including effects such as:

- Mutagenic responses in bacterial strains.
- Morphologic changes in mammalian fetal cells.
- Cytogenic effects on mammalian bone marrow cells.
- Increased gene conversion in yeast species.
- Increased transformation frequencies in mammalian cells.
- Chromosomal damage in cultures of human lymphocytes.

In general, soluble Cr(VI) compounds are less active in the presence of metabolic activating systems. The reduction of Cr(VI) to Cr(III) by cellular agents in metabolic activation systems, in part, explains the reduced mutagenic activity of Cr(VI) in the presence of such activating systems. Some recent evidence implicating both Cr(VI) and Cr(III) in induced mutagenesis has been reported in DNA interaction and DNA polymerase infidelity assays, and several tests with apparently pure Cr(III) samples have found chromosomal aberrations.

Mr. H. M. Howe
Chief Siting Engineer
Pacific Gas & Electric Company
77 Beale Street
San Francisco, CA 94106

Dear Mr. Howe:

Comments on Draft Chromium Report

Thank you for your comments and suggestions on the Draft Chromium Report. We have referred your comments on Part B to the Department of Health Services for response, which, along with your comments and this letter, will be included in Part C of the Report on Chromium to the Scientific Review Panel. We will send you a copy of that report. I am responding to your comments in the same sequence as in your letter.

Page 2, paragraphs 1 and 2: We recognize that the overview table, "Estimated Excess Cancer Burden...", overstates the health impact of ambient hexavalent chromium, because it presents the worst (or upper-bound) case. The table has been removed from the overview. Also, the discussion of excess cancer incidence based on the assumption that all atmospheric chromium is hexavalent has been deleted. We have included an estimate of excess cancer incidence based on ambient chromium(VI) data.

Please note that the Department of Health Services has revised the upper-bound dose-response relationship, and that the ranges of excess cancer risk presented in the overview have been changed accordingly.

Page 2, paragraph 3: Because the fraction of chromium(VI) in total chromium emissions is not known with certainty for some sources, we feel that it is not justified in this report to separately list emissions for hexavalent

June 18, 1985

chromium. We have included whatever information is available on hexavalent chromium emissions in the discussion of emissions for each source. We have revised the report to reflect, in the discussion of fuel-combustion related emissions, that chromium emitted from oil combustion is probably chromium(III). Further research, including source testing to directly measure chromium(VI) and total chromium emissions from oil combustion and other sources, will be an important part of any control program for chromium(VI).

Again, thank you for your comments. If you wish to discuss these comments, or have further questions on the report, please call Cliff Popejoy at (916) 323-8503.

Sincerely,

William V. Loscutoff, Chief
Toxic Pollutants Branch

Re: Comments on Draft Report to the
Scientific Review Panel on Chromium

Dear Bill:

The Western Oil and Gas Association ("WOGA"), a trade association whose members conduct much of the producing, refining, transporting and marketing of petroleum and petroleum products in the western United States, thanks you for the opportunity to submit comments on the draft report to the Scientific Review Panel ("SRP") on chromium. WOGA's review of the draft report leads us to the conclusion that while available epidemiologic data may support a qualitative decision to list hexavalent chromium (chromium VI) as a toxic air contaminant, the available data simply are not of sufficient quality to develop quantitative risk estimates or to form the basis for future risk management.

California law directs the Department of Health Services ("DHS") and the ARB to evaluate the health effects of substances considered for listing as toxic air contaminants and states that the evaluation shall include, among other things, an assessment of the quality of data on health effects. (Health & Safety Code Section 39660(c).) WOGA believes that when, as here, the quality of the available data is questionable, the evaluation should recognize that fact and qualify the conclusions drawn in an appropriate manner. In this way, the accuracy and the confidence that can be placed in the risk estimates will be communicated to the reader of the report. This approach also avoids unduly alarming the public by overstating risks in situations such as this, where relatively high risks are predicted on the basis of results of

MAY 21 1985
REC'D

questionable studies, some of which even showed negative results.

Also, even if chromium VI is listed as toxic air contaminant, as recommended in the draft report, it should not be a foregone conclusion that regulation of emission sources will be required. WOGA asks that the statement on page 10 of the Overview that the identification of chromium VI as a toxic air contaminant will lead to the adoption of toxic control measures be changed to read that identification may lead to the adoption of such measures. This will conform to the statute, which requires that after a substance is listed as a toxic air contaminant, the staff must assess the "need and appropriate degree of regulation" (Section 39665(a)). It will also reflect comments made by ARB members at the January 25, 1985 public hearing on benzene at which it was stated that the Board members did not feel compelled to adopt regulations to control benzene simply because it had been listed as a toxic air contaminant.

With these general thoughts in mind, WOGA submits the following comments on Parts A and B of the draft report.

Part A -- A Review of Chromium Uses, Emissions and Public Exposure.

WOGA's primary concern is with the estimates of average ambient concentrations of chromium in California and their use in the draft report. It appears that the average ambient levels used are too high and that total chromium exposures are given instead of just hexavalent chromium. The end result is that, based on these factors alone, the population risk estimates are six times higher than they should be.

The draft report recommends that only chromium VI be listed a toxic air contaminant, but the ambient exposure data used is for total chromium and therefore the resulting population risk estimates are based on total chromium. The draft report indicates that a maximum of one-third of total chromium is hexavalent chromium, based upon measurements conducted by the ARB in the South Coast Air Basin last year. There is further support for this fact in the Langard study

relied on by the Department of Health Services.¹ That study found that hexavalent chromium comprised approximately 11 to 33% of total chromium emissions in the industrial setting studied.

It also appears the ambient concentrations given for total chromium are too high. The report uses 1977 monitoring data from the Environmental Protection Agency's ("EPA") national aerometric data bank. The staff report states that these measurements were taken throughout California by various public agencies (federal, state and local). The data were collected at different times, by different agencies and, presumably, analyzed by different laboratories. The draft report states that "the accuracy of data contained in the EPA database is not documented." (Draft report at III-1.) The draft report then references more recent data collected by the ARB. The ambient levels recorded by ARB are approximately one-half of those shown by EPA. WOGA believes that this more recent data is more reliable and should have been used in place of the more questionable EPA database.

The use of the EPA database and total, rather than hexavalent, chromium significantly overstates actual exposures to chromium VI. If chromium VI exposure levels were used to develop the population risk estimates, the estimates would be approximately one-third of those shown in the staff report. Likewise, if the more recent ARB ambient monitoring data were used in place of the EPA data, the population risk estimates would be one-half of those estimated by the ARB staff. When both factors are combined, the resulting population risk estimates are six times higher than they should be. This significant overestimate of population risk underscores the need to develop a more accurate picture of ambient chromium VI levels before a population estimate can be developed for use in the risk management phase.

It should also be noted that the draft report states that "intake of chromium from ambient air represents by far the most significant exposure route to chromium, especially for chromium (VI)." (Page III-22.) This does not appear to be accurate based on other information provided in the draft report. For example, the report states that "chromium intake from a typical American diet of 43% fat was determined to be

¹ Langard, S., A. Andersen and B. Gylseth. 1980. Incidence of Cancer Among Ferrochromium and Ferrosilicon Workers. British Journal of Industrial Medicine 114-120.

68 + 28 ug/day; from a typical American diet of 24% fat, intake of chromium was determined to be 89 + 56 ug/day." (Page III-21.) Ambient concentrations are approximately 15 ng/m³ (annual average; Draft Report, Overview, page 4). When the ambient concentrations are multiplied by the amount of air breathed on a daily basis (20 cubic meters/day), the daily exposure to chromium is .3 ug as a result of daily breathing. This is far less than the amounts estimated to occur as a result of diet.

Lastly, more detailed information is needed on emissions of chromium VI from individual point sources. The relative magnitude of chromium VI emissions from sources such as cooling towers needs to be much better defined before it can be determined if a control program is necessary. The draft report estimates that emissions from cooling towers account for between 0.6% to 20% of total chromium emissions from stationary sources. Obviously, this is an imprecise estimate. In addition, WOGA suspects that the effect of chromium VI emissions from cooling towers may be highly localized. Further investigation needs to be undertaken to determine whether chromium VI emissions from cooling towers are carried outside plant boundaries into the ambient air in any appreciable quantities. WOGA offers to participate in such an investigation.

Part B -- Health Effects of Chromium

The epidemiological studies upon which the DHS bases its risk estimates for chromium are not adequate for developing mathematical estimates of risk. Each of the studies relied upon is seriously flawed for one or more reasons. However, these flaws are not adequately discussed by the DHS nor are the risk estimates derived from the studies appropriately qualified.

The limitations in each of the studies used by DHS will be discussed. However, each study is flawed in one of the following general ways:

1. Questionable quantitation and speciation of the exposure estimates. The exposure data is sketchy and is often obtained from a period later than when the cohort was exposed. Therefore, the exposure levels given are probably lower than the actual exposures. From the reports, it is difficult to determine the percentage of chromium VI, even where exposure levels are given or estimated.

2. Exposure to other carcinogens. Confounding factors for lung cancer, principally cigarette smoke or asbestos, were not controlled. The level of "excess risk" supposedly contributed by chromium (unspeciated) is therefore not clear. At the very least, the "unit" risk estimates should be revised to account for these factors or they should be used to qualify the accuracy of the risk estimates.

3. Poor definition of the cohort. In most of the studies, the cohort was loosely defined. For example, there are serious questions as to whether some of the workers studied were exposed to chromium VI at all and the duration of such exposure, if any.

In the paragraphs that follow the major shortcomings of each of the study will be discussed.

1. Pokrovskaya. EPA concludes that "although this study showed a significant increase of lung cancer mortality over the control group, the validity of the data is questionable because the study cohort is not clearly defined." Thus, the study should not be used as a data source for risk estimates. In addition, the study authors reported that workers were exposed to other potentially carcinogenic substances, but no attempts were made to account for these confounding factors.

2. Axelsson. The authors of the study concluded that there was no association between employment in the ferrochromium industry and risk of respiratory cancer. Thus, this study cannot be used in risk estimation. Also, because of the confounding effects of smoking and exposure to asbestos (two of the four cases of respiratory cancer observed were diagnosed as mesotheliomas), no definite conclusions can be drawn from this study about chromium exposure and cancer.

3. Langard. Members of the cohort were also exposed to asbestos. Thus, the author's classification of the observed cases of "lung cancer" is not clear because some of the observed number of cases could have been caused by asbestos instead of chromium and could have included mesotheliomas. In addition, measurements of airborne chromium levels were not taken until 1975 and may seriously underestimate the actual ambient levels to which most of the workers were exposed. EPA's review states that "these concentrations are used in our potency calculations with the understanding that the potency so estimated can only be considered an upper bound estimate." Also, as in the

Pokrovskaya study, the ferrochromium workers may have been exposed to two other carcinogens, asbestos and polycyclic aromatic hydrocarbons.

4. Mancuso. The DHS risk assessment is based primarily on this study, which examined the relationship between exposure to chromium and lung cancer in approximately 300 men employed in a chromate plant between 1931 and 1937. EPA's own review of the study, however, concluded that the observed association between chromium exposure and lung cancer is "based on very small numbers, and thus the finding of a dose-response is probably questionable." The risk associated with exposure to chromium from the application of this study may be overestimated because of the use of 1949 industrial hygiene data and the fact that although lung cancer death was a major outcome of interest, no smoking histories were available for the study cohort.

The 1949 industrial hygiene study mentioned above found the ratio of trivalent chromium to hexavalent chromium to be six. Since only total chromium exposure was measured, and trivalent chromium exposure was assumed to be meaningless, the upper bound of the risk estimate was determined by increasing the "best" estimate by seven fold. On the other hand, EPA felt (and DHS agreed) that using the industrial hygiene data from 1949 may have resulted in overestimating the true exposure levels.² Therefore, the "best" estimate was divided by two as part of the procedure to determine the lower bound of risk. The use of such unjustified factors in quantitative risk assessment to produce specific unit risk estimates creates substantial uncertainty.

In addition, the Mancuso study did not include data on exposures that workers may have had to substances in the plant other than chromium or information on substances the workers may have been exposed to at other facilities or in other occupations.

² The DHS states that the authors of the 1949 industrial hygiene study "noted that it was unlikely that the exposure levels experienced by the study cohort were appreciably different from those measured at the time of their exposure assessment study." However, the EPA review cites the authors of the study as stating that there seem to be "little doubt that atmospheric contamination in the past was greater than in 1949."

William V. Loscutoff
May 20, 1985
Page 7

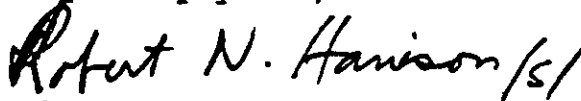

Because of these deficiencies, the use of the data from any of the studies as the basis for risk assessment results in risk estimates that are of dubious validity. It is misleading to present the risk estimates derived in the draft report as plausible upper bounds. The DHS estimates, if used at all, can only be referred to as "worst-case" estimates.

In this regard, it should be noted that the upper limit determined by DHS implies there is a 93% chance of getting cancer from exposure to one $\mu\text{g}/\text{m}^3$ of chromium. This risk estimate is clearly too high to be considered a reasonable estimate. An effect of this magnitude would have been detected in the epidemiologic studies and was not. Even though DHS concedes that the true risk is unlikely to exceed the upper limit of risk, WOGA believes that using 93% as an upper limit of risk does not provide useful information.

WOGA is also concerned about the potential ramifications of listing a substance as a toxic air contaminant when it is not possible to estimate, with any degree of confidence, the risks posed by exposure to ambient levels of the substance. If risk cannot be quantified, it is not possible to make the cost-benefit analysis required in the risk management phase or to decide whether regulation is necessary at all. For this reason, we suggest that chromium VI be moved from a level 1A compound to a level 2 compound until further information is available to quantify the risk estimates.

In conclusion, while the epidemiological data available may support a purely qualitative decision to list chromium VI as a toxic air contaminant, they cannot be used for quantitative risk estimates or to support the decision to regulate emission sources of chromium VI. In addition, the use of ambient data for total chromium, rather than chromium VI, and the use of EPA's ambient data which is twice the ARB levels, overstates the population risk at ambient levels.

Very truly yours,

Robert N. Harrison
Assistant General Manager

AIR RESOURCES BOARD

7 Q STREET
BOX 2815
SACRAMENTO, CA 95812

June 17, 1985

Mr. Robert N. Harrison
Assistant General Manager
Western Oil and Gas Association
727 West Seventh Street
Los Angeles, CA 90017

Dear Mr. Harrison:

Comments on Draft Chromium Report

Thank you for your comments and suggestions on the Draft Chromium Report. We have referred your comments on Part B to the Department of Health Services for response. Their response, your comments, and this letter will be included in Part C of the Report to the Scientific Review Panel on Chromium. We will send you a copy of that report. I am responding to your comments in the same order as in your letter.

Page 2, paragraph 1: We agree, and have changed the report to reflect the fact that identification of a compound as a toxic air contaminant does not compel the Board to adopt control regulations.

Page 2, paragraph 3 and 4: Several people commented, as you did, that the application of dose-response data for hexavalent chromium to total ambient chromium concentrations provides estimates of excess cancer risk which, because they represent worst case or upper bound estimates, are too high. We have revised the overview to include estimates of excess cancer risk which reflect current knowledge of ambient hexavalent chromium concentrations. The resulting risk estimates are approximately one-third the value of the upper-bound estimates.

Please note that the Department of Health Services has revised the upper-bound dose-response relationship, and that the ranges of excess cancer risk have been changed accordingly.

The ARB is working to better characterize ambient levels of chromium(VI) in California. As more temporally and spatially specific data on chromium(VI) concentrations become available, it will be possible to make a better estimate of the health impact of ambient chromium(VI).

Page 2, paragraph 4: The Langard study used by the Department of Health Services to derive a range of dose-response relationships dealt with the chromium pigment production industry. Because there are no chromium pigment production plants in California, it is unclear how the fraction of hexavalent chromium in chromium in the workplace air (or in emissions) of such plants relates to the fraction of hexavalent chromium in total atmospheric chromium in California.

Page 3, paragraph 3: The draft report states that "the intake of chromium from ambient air represents by far the most significant exposure route to chromium, especially chromium(VI)."

As you point out, larger amounts of chromium are received daily in the average diet than are inhaled. However, dietary chromium occurs in the trivalent state, which according to the Department of Health Services, is poorly absorbed and for which there is only weak evidence of carcinogenicity. In comparison, chromium(VI) has been found by the Department of Health Services to be a human and animal carcinogen with no threshold; the theoretical lifetime cancer risk from a continuous 70-year exposure to atmospheric chromium(VI) ranges from 3 to 85 cases per million people per nanogram per cubic meter, with a best estimate of 12 cases per million people per ng/m^3 . Because of this difference in health effects, intake of chromium (particularly chromium(VI)) from ambient air is more important or significant from a health effects standpoint than is chromium(III) intake in the diet.

Page 4, paragraph 2: We agree that an improved emissions inventory will be an important part of any control program for hexavalent chromium. A decision on whether or not to require controls on specific source types will be made during control measure development. We welcome WOGA's offer to participate in investigations of emissions of chromium(VI) from cooling towers, should such investigations be shown to be necessary.

Mr. Robert N. Harrison

-3-

June 17, 1985

Again, thank you for your comments. If you have any questions, please contact Cliff Popejoy of my staff at (916) 323-8503.

Sincerely,

William V. Loscutoff, Chief
Toxic Pollutants Branch
Stationary Source Division

cc: Peter D. Venturini

DEPARTMENT OF HEALTH SERVICES RESPONSE TO COMMENTS:
CHROMIUM HEALTH EVALUATION DOCUMENT

COMMENT I. The meaning of the exposure parameter in the crude risk assessment model needs to be clarified -- substituting the potency factor into the risk model yields a relationship independent of dose (exposure) which is incorrect. (RN Hazelwood, IT Corporation)

Response: The risk assessment model yields a probability and thus is unitless. Therefore, when evaluating the model at a given exposure level, all exposure units cancel. This is exactly what the commenter has shown! The confusion lies in the notation used to describe the potency factor and the risk estimation model -- the exposure estimate used in deriving the potency factor and the exposure level at which the model is being evaluated are both denoted as "d." Thus, when the commenter substituted the potency factor into the risk model the identically designated exposure parameters algebraically cancelled implying that risk is independent of exposure. More appropriately, substituting the potency factor into the risk model yields a ratio of the two exposure parameters wherein the units of exposure will cancel but the risk is still a function of the exposure.

COMMENT II. The Department of Health Services (DHS) has not acknowledged or has not clearly presented the issues related to the quality of the epidemiologic studies used in the risk assessment. This is important because quantitative risk assessment should be based on the highest

quality epidemiologic studies or, in other words, focus on the most valid data. The studies used have deficiencies or problems related to the quantification and speciation of exposure levels, treatment of (potential) confounding factors, definition of the study cohort, definition of lung cancer, small study populations, and in one instance, a study did not find a statistically significant increase in cancer (and is therefore absurd to use in a quantitative risk assessment); therefore, these studies are not acceptable for use in quantitative risk assessment. (Southern California Edison (SCE); California Council for Environmental and Economic Balance (CCEEB); Diamond Shamrock; Allied Corporation; Chevron).

Response: The epidemiologic studies of the health effects of chromium were not designed for quantitative risk assessment. As such, the staff of DHS agrees with the commenters that the studies have deficiencies and limitations when used for this purpose. The staff of DHS also agrees with the commenters (and EPA) who said that the Mancuso study provided the best data for the carcinogenic risk assessment. Since DHS stated that it was adopting the EPA risk assessment (Part B, p 21) which includes discussions of data quality, the Part B report did not repeat this information in great detail nor does the staff of DHS feel such a discussion is warranted. It should be noted that summaries of the studies' limitations were presented (Part B, pp 22-24). However, specific areas of misunderstanding by some of the commenters will be discussed here.

First, the comment was made that in the Mancuso data based assessment, EPA did not adjust for the fact workers' exposures were less than a complete lifetime. This is incorrect as can be seen on pages 7-84 and 7-93 of the EPA report where the factors 8 working hours/ 24 hour day, 240 working days/year, and proportion of lifetime exposed (l/L) are applied to the occupational exposure level.

Second, in the Langard et al study, EPA used a estimate of the relative risk based on a comparison to a plant internal control group rather than using the general population as a reference group. The staff of DHS concurs with EPA in the choice of this control group since it provides the best controls for potential confounding variables such as smoking and socio-economic status.

Third, the inclusion of the Axelsson data was stated as being absurd because it failed to show a statistically significant increase in lung cancer. The staff of DHS acknowledges that the value of epidemiologic studies which do not demonstrate a "significant" effect is controversial; the interpretation ranges from evidence of a threshold to meaningless. However, the staff of DHS disagrees with this blanket statement made by the commenter; a methodologically sound study of this nature can be used with statistical theory to estimate measures of effect that are compatible with data, for example, the 95% upper confidence limit of risk.

In addition, the staff of DHS disagrees, with those commenters who said that the problems with these studies are of a nature that prohibit the use of the studies in quantitative risk assessment. Indeed, EPA has both invoked assumptions to compensate for the major problems in these studies and provided risk estimates based on the uncertainty in the data; with the exception of the Langard et al study (see Comment IV), the estimates of the potency factors are very similar. The effect of these adjustments is reflected in the upper and lower bounds of the theoretical risks presented in the health evaluation.

The staff of DHS further disagrees with the commenter who stated that quantitative risk assessments should strictly be based on the "highest quality epidemiologic studies" since in many cases these studies still do not provide sufficient data to quantify the dose-response relationship (e.g., no exposure data are given). In these cases, animal studies may provide the best estimate of human risk.

COMMENT III. DHS should more clearly state that the risk assessment applies only to the hexavalent form of chromium (Cr(VI)). (CCEEB; Pacific Gas and Electric Company (PG&E))

Response: The DHS risk assessment is strictly applicable to Cr(VI). The confusion seems to lie not in the body of the report but in the document's summary wherein the discussion of risk estimates does refer to Cr(VI) as

does the graphical display of the dose-response curves but the final sentence does not specifically state "hexavalent" chromium. The staff of DHS agrees that this sentence should be modified.

COMMENT IV. The range of risk provided by DHS is problematic; one commenter stated that the range was too broad because it inappropriately provided separate risk estimates derived from the upper and lower exposure levels while only a single risk estimate, based on the "best estimate," should have been given (SCE). Conversely, a different commenter (CCEEB) felt the range of risks provided was too restrictive, particularly for the lowest estimate; a range of risk of 8.4×10^{-4} cancer cases per ug Cr(VI) per cubic meter ambient air (the lower 95% confidence limit of the Mancuso data) to 1.3×10^{-1} cases/ug/m³ (the unadjusted risk estimate from the Langard data) is more appropriate than the DHS range of 3.0×10^{-3} to 9.3×10^{-1} cases/ug/m³. Other commenters (Western Oil and Gas Association; SCE) said that the upper potency factor resulted in risks that were unrealistically high.

Response: The staff of DHS takes exception to the first two statements. With regard to solely presenting the "best estimate," DHS notes that in doing so the assumption is made that there is little or no variability in a worker's exposure, a prospect that would appear very unlikely over an employee's career. Nevertheless, in the absence of complete data for any of

the chromium epidemiologic studies, it is not possible to accurately or precisely state the exposure with great certainty. Hence, the presentation of a single estimate implies that there is a greater degree of certainty with respect to the risk estimate than the data support. On the other hand, the reporting risk estimates based on the range of exposure levels, albeit an estimate of these levels, serves to demonstrate the effect of some of the uncertainty in the data at hand.

The staff of DHS does not agree that the 95% lower confidence limit of a risk estimate should be presented. Such a limit is misleading and attributes a greater certainty to the potential risk than is warranted because the risk is not necessarily bounded by this limit — it may actually be zero.

The staff of DHS agrees with commenters who suggested that the upper risk level was too high. The upper limit of the potency estimates, $2.7/\mu\text{g}/\text{m}^3$, is derived from the Langard et al study. This epidemiologic study applied 1975 exposure data to a cohort of workers comprised of men who were alive as of 1953 and who may have begun working in the plant as early as 1928. In other words, the exposure data probably greatly underestimate the actual exposure which thereby results in an overestimation of the potency and risk. This is supported by the data in Table IV-1 which shows that the risk estimates from the Langard et al study are about 10 times greater than the estimates from the other studies. The EPA health evaluation noted this problem and pointed

out that the potency estimates derived from the Langard study should be interpreted as an upper bound of risk.

The DHS report should have made this explicit. Therefore, the staff of DHS will change Part B to emphasize that the Mancuso data are the focus of its risk assessment and that the other studies are provided for comparative purposes only, that is, because of their deficiencies, they will not be used to calculate the range of risk the staff of DHS recommends to the Air Resources Board.

COMMENT V. The unit risk estimated from the Mancuso study is too high due to the omission of the exposure experience of highly exposed plant maintenance workers, basing exposure levels solely on a 1949 industrial hygiene survey which greatly underestimates the previous 18 year levels and overestimates the subsequent 25 year levels, and fails to include exposure for the period following 1949. This has resulted in a 20-40 fold underestimation of exposure and hence a corresponding overestimation in risk. Animal studies support this overestimation and suggest that the overestimation may be in the range of 42-149 fold. (Allied)

Response: The commenter has raised some valid points but the magnitude of the effect may have been greatly exaggerated as will be shown below. (Since there is incomplete exposure data it is not possible to incontrovertibly resolve this issue.)

First, with respect to maintenance workers, the commenter has suggested that their omission has resulted in a 2-4 fold underestimate of exposure: ([3 hours of exposure/8 hour day] x [5-10 fold higher exposure levels]). The industrial hygiene survey shows that on the average, maintenance workers' exposures were 1-5 times as great as those of production workers (0.45 - 2.32 ug/m³ versus 0.42 ug/m³) with the higher exposures occurring during plant upsets. Since the survey noted that "most" of maintenance workers' time dealt with upsets, the staff of DHS will assume that their average exposure was 5 fold greater than production workers. An overall estimate of a 1.9 fold increase by applying the portion of the day exposed to these levels. The survey also noted that about 30% of the plant work force consisted of maintenance workers. Thus, the overall average exposure for all workers is equal to the weighted average of exposures of the production and maintenance workers or $(.70)[X] + (.30)[1.9X] = 1.3X$, where X is the exposure of the production workers. To summarize, the staff of DHS estimate that the omission of maintenance workers' exposures from the Mancuso data would maximally underestimate the exposure by a factor of 1.3 and not 2-4 times as the commenter has indicated.

Second, the commenter may have also overestimated the impact of the reliance on the 1949 industrial hygiene survey. As used in the EPA risk assessment, the 1949 data represent an average of the exposure for the time period 1931-74. The commenter believes that the pre-survey exposures were up to 5 times greater than at the time of the survey and though they dropped off

considerably in the following years, the post-survey exposure should not be considered equal to 0 as EPA did in their risk assessment. These factors are seen by the commenter to account for a 10 fold underestimation of exposure. However, weighting the exposures by the time periods they were estimated to be present (1931-1949 and 1950-1974) yields only a 2.1 - 2.7 fold underestimate: $([5X][.42] + [1X][.58]) = 2.7$, where X is the 1949 exposure.

Thus, the data used in the Mancuso study are consistent with an overall possible exposure underestimation of 3.5 fold (1.3×2.7). Since the upper risk estimate for this data set includes a 2 fold correction for possible underestimation of exposure, the staff of DHS does not feel this unit risk is significantly overestimated.

The commenter also makes a comparison of risks between a rat intratracheal instillation bioassay of chromium with a benzo[a]pyrene control to the risks stated in the EPA report for these substances to support the assertion that the EPA risk estimate is too high. The ratio of benzo[a]pyrene risk to chromium risk in the rat study ranged from 12 to 42 depending upon which cancers were included in the assessment, however, the EPA report shows chromium as being 3.6 times more potent than benzo[a]pyrene. The commenter then taking the rat study as "truth", that is, benzo[a]pyrene is 12-42 times more potent than chromium, and correcting for the "anomalous" high chromium risk calculated by EPA states that the EPA chromium risk estimate should be reduced by 42-149 times: $([3.6 \times 12] \text{ to } [3.6 \times 42])$. This analysis is

flawed for several reasons. First, the commenter has included a survival parameter in the risk model. The purpose of the parameter as originally derived is to compensate for the apparent reduced risk when a study is prematurely terminated. Its effect on the risk estimate is inversely related to the survival time. However, the rat study was a lifetime exposure bioassay hence, the survival parameter should not have been used. Recalculating the risk without this factor and using the data the commenter cites yields a benzo[a]pyrene-chromium risk ratio of 0.79, that is, as in the EPA report, chromium is a more potent carcinogen than benzo[a]pyrene. (Differences between the EPA cited potencies and those given by the commenter may be due different study protocols and uncertainties in extrapolating animal data to humans.) Furthermore, using the information provided by the commenter to calculate the survival factor yields average proportion of lifetime survived of 0.498 and 0.998 for benzo[a]pyrene and chromium exposed rats, respectively. However, Table 1 of the bioassay report states the average survival times were about 0.75 and 0.95 for the respective substances. Therefore, it is not clear how the commenter calculated the cited risks.

In summary, the arguments raised by the commenter do not support the assertion that the EPA chromium unit risk is too high.

COMMENT VI. Several comments were directed at the assumptions of the low dose extrapolation model. Specific points were raised concerning

linearity of the dose-response curve at low dose, whether evidence exists to support a dose-response relationship both in general and specifically at ambient levels, the appropriateness of using survival data not dependent on chromium exposure, and the model's inability to adjust for potential confounding factors. (CCEEB; Diamond Shamrock)

Response: While many assumptions were invoked to assess the carcinogenic risk posed by hexavalent chromium, by following the peer reviewed EPA report DHS has taken scientifically accepted positions. Nevertheless, a brief response to the issues raised by the commenters will be given.

First, the assumption of low dose linearity is not amenable to empirical verification in either human or animal species rather, it is an accepted scientific practice particularly when extrapolating from human data. As such, it is possible to estimate health effects at ambient levels from data obtained from higher exposure levels and to use a linear model to do so.

Second, with respect to the demonstration of a dose-response relationship, the paucity of worker exposure ("dose") information in epidemiologic studies and the lack of a good animal model for inhalation exposure for other species, even though each of these study groups has clearly demonstrated the carcinogenic potential of Cr(VI), has hampered attempts to show a dose dependent response. The observation that no relationship has been shown for ambient exposure levels is a function of several factors not the least of which is that it has not been looked for! Only one epidemiologic study was

found which addressed lung cancer and ambient chromium exposures. While this ecologic study found no association, several criticisms of this study are noteworthy: exposure data were sparse and did not differentiate between trivalent and hexavalent chromium although it was likely most of the exposure was to Cr(III), migration was considered unimportant when in reality it serves to diminish any association, and statistical power was low. Thus, the staff of DHS does not believe that the absence of evidence is sufficient evidence of the absence of a dose-response relationship.

Third, the meaning of the survival term in the competing risks model $A(s)$ has been misinterpreted by the commenter. The probability of surviving to age s is contingent on not having died prior to this age from any cause including exposure to chromium (Cr(VI)). In other words, it implicitly includes the assumption that there has been and continues to be exposure. The risk of dying after age s is then the product of the probability of surviving to s and the risk of dying in this time interval from disease (cancer) related to the chromium exposure. This is what the formulation of the model shows (Part B, p 25).

Fourth, the commenter is correct in noting that the extrapolation models per se cannot directly adjust for covariates. However, that does not preclude indirect adjustment, as the EPA has done, for the effect of smoking in the Mancuso data or by excluding cases of mesotheliomas from the Axelsson data since they probably resulted from asbestos exposure. It is noteworthy that EPA's treatment of potential confounding variables is based on information

presented in peer reviewed scientific literature. In general, the staff of DHS finds it difficult to disregard a risk model which did not rigorously treat potential confounders, such as cigarette smoking and asbestos, even though the studies did not collect any data on these factors.

COMMENT VII. Comments were made regarding the statement that there was not sufficient evidence to demonstrate a carcinogenic threshold for Cr(VI). Several commenters stated that there was substantial evidence in support of this concept stemming from animal studies (which demonstrate site of contact tumors only and observing no (lung) tumors in 80 animals receiving 0.25 mg/kg sodium dichromate 5 days per week for life) and metabolism and/or detoxification studies of chromates (which show Cr(VI) reduced to Cr(III) under physiologic conditions and noting that Cr(III) is non-mutagenic). Further support comes from the existence of occupational threshold limit values (TLVs) and permissible exposure levels (PELs). (Allied; Diamond Shamrock; Ad Hoc Environmental Group (glass manufacturers))

Response: The staff of DHS does not disagree that one interpretation of the animal and metabolic studies cited is consistent with the concept of a carcinogenic threshold but, the information cited by the commenter is not conclusive proof that a threshold exists. Indeed, as one commenter stated, the animal and metabolic evidence "...does not permit quantification of the threshold or description of the dose-response relationship at low doses."

This suggests that even if a threshold exists, current data are insufficient to determine what that level would be. Moreover, the staff of DHS does not accept the argument that the existence of TLVs or PELs for chromium compounds support the threshold concept. The exposures denoted by TLVs and PELs represent acceptable exposure levels for the workplace and not threshold levels; indeed, the question of the existence of a carcinogenic threshold is not usually considered in setting these exposure levels. Also, because TLVs and PELs are developed for occupational settings, these standards allow for higher risks than are, as a rule, permitted for the general population under ambient exposures.

Therefore, in the absence of both the knowledge concerning the mechanism of action and conclusive proof to the contrary, the staff of DHS leans towards the health protective intent of California's Health and Safety Code section 39650 in saying a threshold has not been established for hexavalent chromium.

COMMENT VIII. The report should draw a clearer distinction between various Cr(VI) containing materials especially in terms of chromate pigments where there is evidence showing that not all chromate pigments provide the same hazard. For example, very insoluble lead chromate based pigments conveyed less cancer risk than the more soluble chromate compounds in an animal study. Indeed, one epidemiologic study showed no statistically

significant increase in cancer from the manufacture of lead chromate.

(PA Wriede, Heubach Inc.)

Response: The staff of DHS acknowledges that the carcinogenic potency of different Cr(VI) compounds may not be identical, however, current epidemiologic data do not permit distinction among the compounds for purposes of quantitative risk assessment involving airborne exposure. Animal studies present the most suggestive evidence of a compound specific response. However, they are not used for the chromium risk assessment because of difficulties related to determining dose levels to use in the assessment where the route of exposure was implantation (see Part B, p 21 for further discussion of this point). With respect to the epidemiologic studies, few have attempted to distinguish among different compounds and those that have done so tended to be inadequately reported and include only small populations of workers. The International Agency for Research on Cancer (IARC) has concluded, and the staff of DHS concurs, that the current epidemiologic data do not allow an evaluation of the chromium carcinogenic risk based on compounds having different solubilities.

COMMENT IX. There is no human evidence that chromium compounds are associated with teratogenesis. The older animal studies which have reported teratogenic effects should be evaluated relative to dose and maternal toxicity. (Diamond Shamrock)

Response: The two teratogenic studies reported in Part B deal with subcutaneous and intravenous routes of exposure which are not directly applicable to environmental exposure to chromium. They were cited for completeness only. Based on these studies it is possible that Cr(VI) may be teratogenic but this would only occur at levels far exceeding ambient exposures or at doses which are maternally toxic.

COMMENT X. The modifiers "weakly" and "highly" should not be used to describe the mutagenic effects of chromium. The report should provide an indication as to how chromium compared to other mutagens. (Diamond Shamrock)

Response: The terms "weakly" and "highly" were used with reference to the number of test systems in which chromium gave a positive mutagenic response. Although qualitative in nature, since no positive controls were used in the assays, there are no data with which to more precisely describe the mutagenic activity of chromium relative to other mutagens.

Attention: MEMBERS OF THE SCIENTIFIC REVIEW PANEL

Subject: Report to the Scientific Review Panel on Chromium

Southern California Edison would first like to state that we believe the public was allowed insufficient time to review and prepare comments on this complex and important report. Members of the public had only three (or less) working days to review the revised report and prepare written comments. Although we obtained the report as soon as possible after receiving notice that it was available, it was not possible to submit comments to the ARB in time for them to reach panel members prior to the September 26 meeting. Panel members will now first review and consider public comments at their meeting held to take action on the document. We do not believe that this method of operation is in accord with the intent of AB1807. We recognize the ARB's desire to proceed with these reviews in a timely manner and realize the constraint of time schedules written into state law. We believe, however, that some provision must be made to allow public input to the process when the intent of the law was to do just that.

While we did not have sufficient time to prepare extensive comments, we offer the following general comments on the Report to the Scientific Review Panel on Chromium.

This report concludes that hexavalent chromium should be treated as a substance without a carcinogenic threshold. A recent publication on the metabolism of hexavalent chromium, which we have included as an attachment to these comments, should be considered in this context. Research by Petrilli et. al. (see attachment) indicate that, in addition to already recognized detoxification mechanisms operating outside target cells, specific and inducible chromium-reducing pathways mediating threshold phenomena in chromium carcinogenesis (e.g. mutagenesis) do also occur in the intracellular environment.

We wish to bring this recent data to the attention of the SRP since it can be useful in evaluating the carcinogenic potential of chromium compounds at low doses.

The Overview and Recommendation section of the DHS report states:

"...the theoretical lifetime cancer risk from a continuous 70 year exposure to atmospheric hexavalent chromium (chromium VI) exposure ranges from 12 to 146 cases₃ per million people per nanogram per cubic meter (ng/m³)."

We feel this statement is very misleading. The commonly accepted meanings for the word "range" include "the full extent covered by something" or "to vary within specified limits" or "the class of admissible values of a variable". The values presented in this report represent only the mid-to-upper limits of risk. Consideration of factors such as the impact of smoking in the Mancuso study worker population or underestimation of their exposure to hexavalent chromium, factors which would lead to lower estimates of risk, have been systematically excluded in the development of this "range" (Section 8.3.8 - Summary of the Risk Assessment). A more factual estimate of the "range" of risk would extend from the lowest to the highest scientifically reasonable risk estimates. If a more conservative risk range estimate is proposed, the following statement, which currently appears on page 98 of Part B of the report, should be included in the Overview and Recommendation section.

"The staff of the DHS does not present a lower confidence limit for potency estimates because the true risk may be considerably below even the lower boundary of the 95% confidence interval limit, yet there is no scientific basis for locating this risk."

SCE appreciates this opportunity to provide comments during the development of this important document. It is our hope that more time will be allowed for public input in the development of future reports.

Sincerely,

Edward J. Farchy

Specificity and Inducibility of the Metabolic Reduction of Chromium(VI) Mutagenicity by Subcellular Fractions of Rat Tissues¹

Fernando Luigi Petrilli, Anna Camoirano, Carlo Bennicelli, Patrizia Zancacchi, Marina Astengo, and Silvio De Flora²

Institute of Hygiene, University of Genoa, Via Pastore 1, 16132 Genoa, Italy

ABSTRACT

The mutagenicity of sodium dichromate in the Ames test was decreased as a consequence of chromium(VI) reduction by tissue postmitochondrial (S-9 or S-12) fractions from untreated rats with the following rank of efficiency: liver; kidney; and lung. The effects of lung preparations were significantly enhanced following the intratracheal administration of high doses (0.25 mg/kg) of dichromate itself, 5 times per week for 4 weeks (i.e., 20 fractionated instillations). No changes were conversely detected following single weekly doses of 1.25 mg/kg for the same period (i.e., four cumulative instillations). The local stimulation of chromium(VI) metabolism was also confirmed by testing the mutagenicity of calcium chromate and chromium trioxide, whereas the metabolism of a number of other activatable or deactivatable mutagens was not significantly affected by intratracheal treatment with chromium(VI). Of three enzyme inducers injected i.p. which modified the spectral properties and/or concentration of cytochromes P-450 in liver and lung microsomes, only Aroclor 1254 proved to stimulate chromium(VI) metabolism in lung cells. In liver cells, Aroclor 1254 and to a lower extent phenobarbital induced chromium(VI) reduction, while 3-methylcholanthrene was ineffective. Pretreatment of rats with these three compounds resulted in a selective induction of the metabolic activation of promutagens [benzo(a)pyrene and its *trans*-7,8-diol, 2-aminofluorene, aflatoxin B₁] and of the metabolic deactivation of direct-acting mutagens [2-methoxy-6-chloro-9-[3-(2-chloroethyl)aminopropylamino]acridine·2HCl, epichlorohydrin, 4-nitroquinoline-*N*-oxide] by S-12 and microsomal fractions. These findings indicate that, in addition to already recognized detoxification mechanisms operating outside target cells (26), specific and inducible chromium-reducing pathways, mediating threshold phenomena in chromium carcinogenesis, do also occur in the intracellular environment.

INTRODUCTION

Both epidemiological and experimental data suggest that chromium compounds may possess carcinogenic properties (13, 14). However, an adequate demonstration of carcinogenicity in animals is available only for a limited number of chromium(VI) compounds, and no conclusion can be drawn about the responsibility of specific chromium compounds in inducing lung cancer in occupationally exposed individuals.

Short-term test systems have provided a useful tool for identifying potentially carcinogenic compounds and for elucidating their mechanisms. With very few exceptions, chromium(III) com-

pounds have been reported to be inactive in cellular systems, while chromium(VI) compounds have been consistently found to exert, both *in vivo* and *in vitro*, mutagenic and clastogenic effects in a variety of prokaryotic and eukaryotic cell systems, as well as DNA damage and cell transformation (13, 14, 19, 25). In the Ames reversion test, once solubilized in water or alkali, all the chromium(VI) compounds tested appear to share very similar features, i.e., the same spectrum of sensitivity of his⁻ *Salmonella typhimurium* strains, the same order of magnitude of mutagenic potency, as well as the same trend to a decrease of mutagenicity in the presence of metabolic systems (6, 26). These patterns clearly indicate the responsibility of the hexavalent ion in producing genetic effects. However, solubility of chromium compounds, when introduced into an organism under crystalline form, is expected to play an important role *in vivo* by affecting their rate of absorption, distribution, retention, metabolism, and clearance.

The metabolic fate of chromium is of particular concern for predicting and interpreting the *in vivo* effects of this metal. Since the first demonstrations that the direct mutagenicity of chromium(VI) can be decreased by rat liver S-9 fractions (5, 12, 20, 23), many efforts have been devoted to assay the possible interconversion processes between the hexavalent and the trivalent forms. In the past years, we have been investigating the mutagenicity of several chromium compounds in the presence of up to 40 metabolic systems, including body fluids and subcellular fractions from various tissues of humans and other animal species, also under the influence of special diets or treatments, diseases, or drugs. No metabolic activation of chromium(III) could be detected (24), while the mutagenicity of chromium(VI) was markedly decreased by liver preparations from humans, rodents (rat, mouse, hamster, woodchuck), chicken, and fish (Refs. 8 and 26; Footnote 3). Preparations from other tissues and body fluids were also capable, to a variable extent, of reducing chromium(VI) and of lessening its genetic effects.

In a separate paper (9), we are describing the possible biochemical mechanisms responsible for the metabolic reduction of chromium. In this paper, we provide evidence that this metabolic process is specific and that it can be selectively stimulated not only by known enzyme inducers but also, in lung cells, by the repeated i.t.⁴ administration of high doses of chromium(VI) itself.

The data herein reported were obtained in 2 consecutive studies. The first one (referred to as Study A) aimed at assessing the decrease of chromium(VI) mutagenicity in the presence of

³ F. L. Petrilli, A. Camoirano, C. Bennicelli, P. Zancacchi, M. Astengo, and S. De Flora, unpublished data.

lung, liver, and kidney S-9 fractions from rats treated i.t., according to various schedules, with NaCl or sodium dichromate. The second (Study B) aimed at confirming the stimulating effects of i.t. dichromate on chromium(VI) pulmonary metabolism and at comparatively assessing the extent of its reduction by liver and lung S-12 fractions from rats treated i.p. with enzyme inducers. The spectra and concentrations of cytochromes P-450 were determined in the corresponding microsomal fractions. The efficiency and specificity of treatments were also checked by evaluating the ability of subcellular fractions in activating promutagens (BP, BP 7,8-diol, 2AF, AFB1) or in decreasing the mutagenicity of direct-acting compounds (4NQO, ICR 191, ECH) in the Ames test.

MATERIALS AND METHODS

Chemicals. Sodium dichromate ($\text{Na}_2\text{Cr}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$) used for the i.t. treatment of rats was obtained from Bredel-De Haen AG, Merck, Darmstadt, Federal Republic of Germany. It was dissolved, at the concentrations indicated in Table 1, in a 0.9% NaCl solution.

The 3 enzyme inducers, dissolved in corn oil, were PB (E. Merck AG), MC (Fluka AG, Buchs, Switzerland), and the PCB AR (Anatabs, Inc., North Haven, CT).

The compounds assayed in the Ames test were sodium dichromate and chromium trioxide (CrO_3) (Merck-Schuchardt, Munich, Federal Republic of Germany), calcium chromate (CaCrO_4) (BDH, Poole, England), 2AF and BP (Ega-Chemie KG, Steinheim/Albuch, Federal Republic of Germany), BP 7,8-diol and 4NQO (kind gift of Dr. D. G. Longfellow, National Cancer Institute, Bethesda, MD), AFB1 (Sigma Chemical Co., St. Louis, MO), ECH (Carlo Erba, Milano, Italy), and ICR 191 (Polyscience, Inc., Warrington, PA).

Treatment of Rats. Treatment of 10-week-old male Sprague-Dawley rats was carried out at the Institute of Toxicology of Bayer AG (D-5600 Wuppertal, Federal Republic of Germany) by Dr. D. Steinhoff. The treatment schedule is reported in Table 1.

The i.t. application, consisting of a volume of 1 ml/kg body weight, was performed on rats anaesthetized with ether, as described in more detail by Steinhoff *et al.*⁹ The rats were supplied with tap water and Altromin standard diet (Altrogge 4937 Lage) *ad libitum* throughout the period of treatments. During the last 12 h before sacrifice, rats were starved and permitted water.

Preparation of Subcellular Fractions. Irrespective of the treatment schedule, all the rats were sacrificed 24 h after the last i.t. or i.p. administration, with the exception of those receiving AR, which were killed 5 days after its injection. Lungs and liver (Study B) and additionally kidneys (Study A) were aseptically collected from each rat, following anesthesia with ether and killing by decapitation and bleeding. All the subsequent steps were carried out at 0–4°C, using sterile glassware and solutions and operating under aseptic conditions.

Immediately after removal, the organs were washed in flasks containing a 10 mM Tris-0.15 M KCl solution, pH 7.4, transferred into beakers containing 10 ml of the same solution, and finely minced with scissors. Minced organs were wiped on gauze, weighed, and immersed in 3 volumes (*i.e.*, 3 ml/g of wet tissue) of a 50 mM Tris-0.25 M sucrose solution, pH 7.4. Homogenates were prepared using a Potter-Elvehjem apparatus with glass tubes and Teflon pestles (5 strokes).

Homogenates were centrifuged twice for 20 min at 9,000 × g (Study A) or 12,000 × g (Study B). The supernatants (S-9 or S-12 fractions, respectively) were divided into small aliquots and stored at –80°C.

In Study B, aliquots of liver and lung S-12 fractions from each of the 6 experimental groups were further pooled, gauze filtered, and centrifuged twice for 1 h at 105,000 × g using 2 Beckman Spinco L2-65B

ultracentrifuges. The microsomal pellet was resuspended, in the proportion of 0.5 ml per g of original tissue, in a 50 mM Tris-0.1 mM EDTA solution, pH 7.4, supplemented with 20% glycerol, divided into small aliquots, and frozen at –80°C.

The protein concentration in S-9, S-12, and microsomal fractions was measured according to the protein-dye method of Bradford (3).

Determination of Cytochromes P-450. The amounts and the spectral properties of cytochromes P-450 in liver microsomes were determined by means of the classic method (2): evaluating CO binding to cytochrome reduced with dithionite. Cytochromes P-450 in pulmonary microsomes were determined according to a specifically designed method (16) involving reduction of methemoglobin with ascorbate and phenazine methosulfate prior to bubbling CO and adding dithionite.

Mutagenicity Assays. The effects of the various subcellular fractions on the mutagenicity of chromium(VI) compounds were investigated in the Ames test, basically following the standard plate incorporation test (21). Since we have recently demonstrated that TA102, a newly developed *S. typhimurium* strain which is efficiently reverted by oxidative mutagens (13), is even more sensitive to chromium(VI) than TA100 (2), both strains were used in the more recent experiments.

Since the decrease of chromium(VI) mutagenicity is more pronounced following liquid preincubation with metabolic systems (9), dichromate (10 to 50 µg/plate in 100 µl of distilled water) was preincubated for 1 h at 37°C with subcellular fractions (20 to 200 µl/plate) incorporated in S-9 mix (0.5 ml/plate), prior to application on target cells and embedding in top agar. S-9 mix had the standard composition (21) when combined with S-9 or S-12 fractions, and it was supplemented with 4 IU of yeast G6PD when combined with microsomal fractions.

The other compounds tested were assayed at the concentrations and with the *S. typhimurium* strains indicated under "Results." Mutagens requiring metabolic activation (*i.e.*, 2AF, BP, BP 7,8-diol, and AFB1, all dissolved in DMSO) and a nonmutagenic chromium(III) compound (*i.e.*, chromium acetate, dissolved in water) were directly mixed with metabolic systems, bacteria, and molten top agar according to the standard procedure (21). Mutagens undergoing metabolic deactivation (*i.e.*, calcium chromate, chromium trioxide, ECH, and ICR 191, all dissolved in water, and 4NQO dissolved in DMSO) were preincubated with the metabolic systems as described for dichromate.

All the mutagenicity assays were performed in triplicate plates.

RESULTS

Effect of Treatments on Weight of Organs, on the Protein Concentration in S-9 and S-12 Fractions, and on Cytochromes P-450 in Liver and Lung Microsomes. As shown in Table 1, the i.t. treatments, either with NaCl or with sodium dichromate, had no significant influence, as checked both by ANOVA and by Student's *t* test, on the mean values of weight of organs and on the protein concentration in the corresponding S-9 (Study A) or S-12 (Study B) fractions. Conversely, the i.p. treatment with PB, MC, and AR resulted in a statistically significant increase in liver weight. Such increase was particularly pronounced in the case of AR, which additionally determined an increase in the protein concentration of the corresponding S-12 fractions (significant at the 0.05 level).

Table 1 also shows the wavelength of the peaks of cytochromes P-450 and their concentration in liver and lung microsomes obtained from the 6 experimental groups under scrutiny in Study B. The methods used proved to be very accurate in resolving and discriminating the peaks of cytochromes, as related to treatment of rats. In fact, the peak was consistently at 450 nm for the liver microsomes of untreated rats and of rats treated with NaCl, $\text{Na}_2\text{Cr}_2\text{O}_7$, or PB, while it shifted to 448 to 448.5 nm

in samples from MC-treated rats and to 449 to 449.5 nm in samples from AR-treated rats. The peaks yielded by lung microsomes showed the same or a slightly increased wavelength (0.5 to 1 nm), as compared with liver microsomes.

The concentration of cytochrome P-450 was considerably higher (11- to 24-fold, depending on treatment of rats) in liver than in lung microsomes. The 2 procedures used for liver (22) and lung (16) preparations yielded similar figures, from both qualitative and quantitative standpoints, when comparatively assayed with liver microsomes. The mean increase in cytochrome P-450 levels in hepatic microsomes (based on 3 to 5 assays per sample) was significant in animals treated i.p. with the 3 enzyme inducers and was particularly pronounced in the AR group. Both MC and AR induced a slight increase in P-450 concentration also in pulmonary microsomes, but such increase was statistically significant for the latter inducer only. Neither NaCl nor Na₂Cr₂O₇ i.t. affected to a significant extent P-450 levels in liver or lung microsomes.

Decrease of Dichromate Mutagenicity in the Presence of Lung, Liver, and Kidney S-9 Fractions from Rats Treated i.t. with NaCl or with Dichromate Itself (Study A). In the absence of metabolic systems, sodium dichromate induced a dose-related mutagenic response in strain TA100 of *S. typhimurium*, with a narrow range of active concentrations (20 to 40 µg/plate) and occurrence of toxic effects (absence or marked sparing of the background lawn of bacterial growth) at 50 µg/plate. Addition of S-9 mix containing lung, kidney, or liver S-9 fractions from the variously treated rats resulted, to a variable extent, in an evident decrease of mutagenicity and in the conversion of toxic into mutagenic effects at the highest dose tested. An example of results obtained is shown in Chart 1.

In particular, liver preparations (which were examined only in the 3 groups of animals treated 5 times per week) were the most efficient in decreasing dichromate mutagenicity. At 100 µl/plate (Chart 1), their preincubation with dichromate, even at 50 µg/plate, resulted in an almost complete loss of mutagenicity, without any significant difference among the 3 i.t. treatments under scrutiny. Even by lowering the amounts of liver S-9 fractions to 50 or 25 µl/plate (data not shown), in order to obtain an incomplete reversal of mutagenicity, no significant difference could be detected among the 3 groups (F > 1, P > 0.05).

The kidney S-9 fractions obtained from the same 3 experimental groups were clearly less active than liver S-9 fractions in decreasing dichromate mutagenicity but, despite the slightly lower protein concentration (see Table 1), they were more efficient than the corresponding lung preparations (Chart 1). As for the liver, no significant difference (F > 1, P > 0.05) could be detected by preincubating varying amounts of chromium(VI) with S-9 fractions pooled within each group (Chart 1), nor in other experiments evaluating the metabolic activity of all the individual kidney preparations with fixed amounts of chromium(VI) (data not shown).

Lung S-9 fractions were prepared from the animals treated i.t. for 4 weeks with NaCl or varying amounts of dichromate, once per week (2 groups) or 5 times per week (3 groups). The ANOVA revealed significant differences, on the whole (F = 59.62, P < 0.001), in the number of revertants induced by varying amounts of dichromate in the presence of S-9 fractions pooled from the 5 experimental groups. In particular, orthogonal comparisons of the mean values shown in Chart 1 provided evidence that the

4 (Not shown)	30	4.86	>0.05	1.50	>0.05

^a T5, rats receiving sodium dichromate (0.25 mg/kg) i.t. 5 times per week for 4 weeks; T3, rats receiving 0.9% NaCl solution i.t. 5 times per week for 4 weeks; T4, rats receiving sodium dichromate (0.05 mg/kg) i.t. 5 times per week for 4 weeks.

decrease of mutagenicity is significantly more pronounced in the group of rats receiving dichromate (0.25 mg/kg) 5 times per week, as compared to the other 4 groups, at all the concentrations of dichromate positive in the Ames test, i.e., 50 µg ($F = 96.66, P < 0.001$), 40 µg ($F = 71.94, P < 0.001$), 30 µg ($F = 48.85, P < 0.001$), and 20 µg ($F = 20.36, P < 0.01$) per plate. Although to a lower extent, lung S-9 fractions from rats receiving NaCl 5 times per week showed an increased efficiency, compared to the remaining 3 groups, in reducing dichromate mutagenicity at 50 µg ($F = 11.77, P < 0.01$), 40 µg ($F = 12.64, P < 0.01$), and 30 µg ($F = 6.88, P < 0.05$) per plate.

Several other experiments confirmed that, in general, the lung S-9 fractions from rats treated 5 times per week were significantly more active than those from rats treated once per week and that, within the former group, the metabolic activity was the highest in the animals receiving dichromate (0.25 mg/kg).

Table 2 reports the results of a statistical analysis of 4 separate experiments with lung preparations from rats treated 5 times per week. One of these (the one summarized in Chart 1) was carried

out by testing the mutagenicity of varying amounts of dichromate in the presence of lung S-9 fractions pooled from the 3 groups, whereas the other 3 (Experiments 2 to 4) were carried out by testing the mutagenicity of a fixed amount of dichromate in the presence of the 15 individual lung S-9 fractions, all of them in triplicate plates. It can be observed that, with the exception of Experiment 4, the i.t. treatment with the higher dose of dichromate (T5) resulted in an increased metabolic efficiency of lung preparations, as compared with administration of its solvent (NaCl) (T3). On the other hand, with the exception of Experiment 1 (at one dose level only), no significant difference was apparent between T3 and T4 (lower dose of dichromate).

Decrease of Dichromate Mutagenicity in the Presence of Lung and Liver S-12 Fractions from Rats Treated i.t. with NaCl or with Dichromate Itself or i.p. with 3 Enzyme Inducers (Study B). As in the previous study, liver preparations were markedly more efficient than lung preparations in decreasing dichromate mutagenicity and were therefore tested in low amounts (20 to 25 µg/plate) in order to point out possible metabolic differences attributable to the various treatments of rats. Again, such a phenomenon was investigated by testing both fixed amounts of dichromate with all the individual S-12 fractions (30 of lung and 30 of liver) and varying amounts of dichromate with S-12 fractions pooled from the 6 experimental groups.

In Study B, neither the repeated i.t. administration of NaCl nor the i.p. injection of MC had any influence on the decrease of chromium(VI) mutagenicity by liver or lung preparations, as compared to untreated controls. Conversely, in all experiments performed, AR induced a highly significant ($P < 0.001$) stimulation in both the liver and, generally with more attenuated effects, the lung PB, although less efficiently than AR, also enhanced the metabolic effects in the majority of the experiments performed with liver S-12 fractions (once $P < 0.001$, twice $P < 0.01$, twice $P < 0.05$, and once $P > 0.05$). A borderline effect ($P = 0.05$) was observed in the lung of PB-treated rats in only one of 6 experiments. An opposite trend was observed in rats receiving 20 i.

METABOLIC DECREASE OF CHROMIUM(VI) MUTAGENICITY

doses of dichromate. In fact, no change of chromium(VI) metabolism occurred in the liver, while a stimulation was consistently detected in the lung, in agreement with the results of Study A. Such metabolic enhancement (which quantitatively approached the one afforded by AR in the same tissue) was statistically significant, as compared to lung preparations from untreated or NaCl-treated rats, in all the experiments performed (twice $P < 0.001$, twice $P < 0.01$, and twice $P < 0.05$).

Chart 2 shows an example of dose-response curves obtained with sodium dichromate in the Ames test, in either the absence or the presence of liver and lung S-12 fractions from variously treated rats. For the sake of visual clarity, only the treatments leading to a significant stimulation of chromium(VI) metabolism are reported. As already described, they are: i.p. AR and i.p. PB for the liver; i.p. AR and i.t. dichromate for the lung.

Effect of Lung S-12 Fractions from Rats Treated i.t. with Dichromate on the Mutagenicity of Other Chromium Compounds. Assays with strain TA102 of *S. typhimurium* confirmed

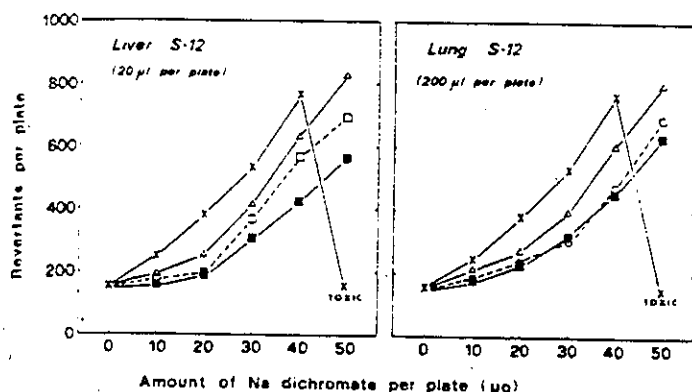

Chart 2. Dose-response curves obtained by testing varying amounts of sodium dichromate (Study B), preincubated for 1 h at 37°C with S-9 mix containing either a 50 mM Tris-0.25 M sucrose solution (controls of dichromate mutagenicity in strain TA100 of *S. typhimurium*; x) or S-12 fractions pooled from rats treated as follows: Δ , untreated; \circ , $\text{Na}_2\text{Cr}_2\text{O}_7$ i.t. (5×0.25 mg/kg/week); \square , PB i.p. (3×60 mg/kg/day for 3 days); \blacksquare , AR i.p. (1×500 mg/kg). Confidence limits are not shown for the sake of visual clarity.

the enhanced decrease of dichromate mutagenicity by lung S-12 fractions of rats treated i.t. with dichromate itself and showed a similar behavior also for the 2 other chromium(VI) compounds tested, i.e., calcium chromate and chromium trioxide (Table 3). In terms of revertants per plate, the differences recorded for each compound between lung preparations from NaCl- and dichromate-treated rats were not statistically significant, although they approached the 0.05 significance level. However, the differences were significant ($P = 0.01$ by Student's *t* test) when the values obtained with the 3 compounds were all analyzed together. Furthermore, similar trends were confirmed in additional experiments. A chromium(III) compound, i.e., chromic acetate, was inactive in both the absence and the presence of lung S-12 fractions, even when tested up to 100-fold-higher doses on a molar basis, compared to chromium(VI) compounds.

Efficiency of Liver and Lung S-12 Fractions from Variously Treated Rats in Activating Promutagens or in Deactivating Direct-acting Mutagens. The same S-12 fractions used for investigating chromium(VI) metabolism were also checked for their efficiency in activating 3 promutagens (2AF, BP, and BP 7,8-diol) and in deactivating 3 direct-acting mutagens (ICR 191, ECH, and 4NQO) in the Ames test.

As shown in Chart 3, each one of the 3 promutagens was tested in the presence of 3 different amounts of S-12 fractions (50, 100, and 200 μl for the lung; 25, 50, and 100 μl for the liver). Lung S-12 fractions failed to activate BP and BP 7,8-diol and were poorly active in converting 2AF into mutagenic metabolites, without any appreciable difference among the 6 experimental groups.

The aromatic amine was activated to a similar extent by 25 and 50 μl of liver S-12 fractions per plate from untreated rats and from rats receiving NaCl, $\text{Na}_2\text{Cr}_2\text{O}_7$, or MC. The efficiency of metabolic activation was further increased following pretreatment of rats with PB or AR. With the latter inducer, the highest mutagenic response was obtained with 25 μl of liver preparations per plate.

The liver S-12 fractions from untreated, NaCl-, or $\text{Na}_2\text{Cr}_2\text{O}_7$ -

METABOLIC DECREASE OF CHROMIUM(VI) MUTAGENICITY

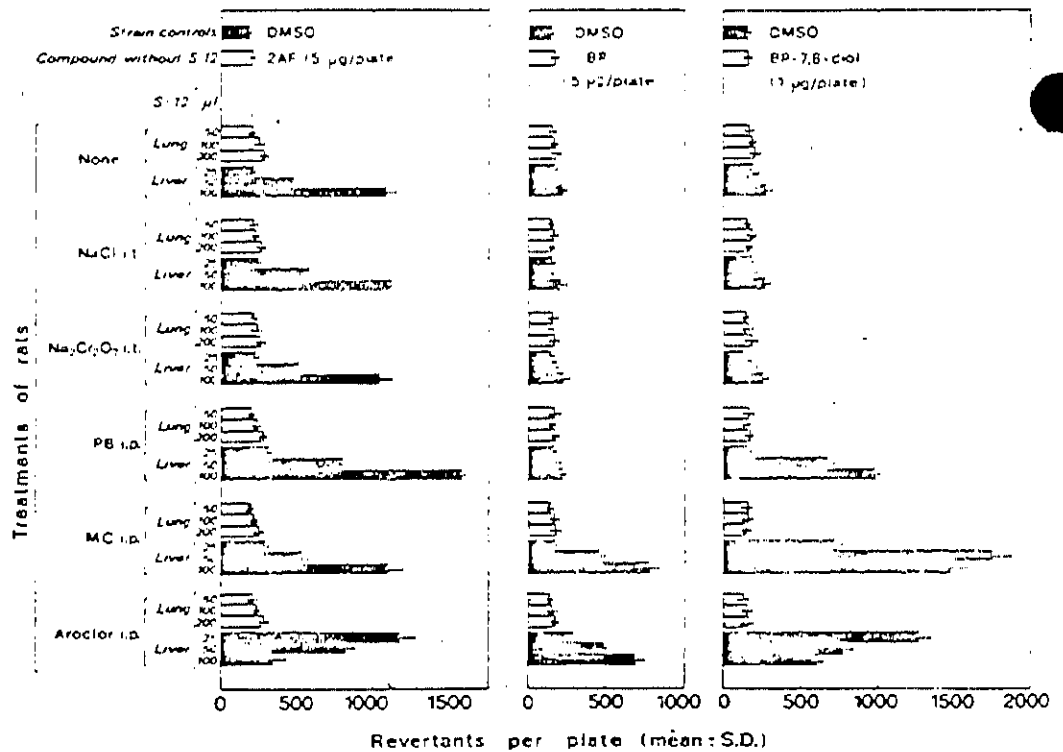

Chart 3. Effect of S-9 mix, containing varying amounts of liver or lung S-12 fractions from variously treated rats, in activating 3 promutagens to mutagenic metabolites in strain TA100 of *S. typhimurium*.

Chart 4. Effect of S-9 mix, containing liver or lung S-12 fractions from variously treated rats, in decreasing the activity of 3 direct-acting mutagens in various strains of *S. typhimurium*.

treated rats showed only a marginal ability in activating the 2 PAHs. Liver preparations from PB-treated rats activated BP 7,8-diol but not BP, whereas AR and MC were highly efficient in stimulating the metabolic activation of both PAHs.

The effects of liver and lung S-12 fractions from the 6 experimental groups on the mutagenicity of 3 direct-acting compounds are shown in Chart 4. The mutagenicity of ECH was only marginally affected by lung preparations, with some more evident consequences following AR treatments. Conversely, all the liver preparations decreased the mutagenicity of this epoxide, and such an effect was more pronounced following PB and especially

AR treatment. 4NQO was deactivated by both liver and, to a lower extent, lung preparations, without any appreciable difference among the 6 groups excepting, again, some further stimulation by AR. All 3 enzyme inducers stimulated ICR 191 deactivation by liver S-12 fractions, with the following rank of efficiency; AR (which completely reverted its mutagenicity); MC; and PB. The most interesting finding in this series of assays was that some stimulation of ICR 191 deactivation by lung S-12 fractions was afforded by not only AR but also (and even to a larger extent) the i.t. pretreatment of rats with dichromate. The difference recorded between NaCl- and dichromate-treated rat

METABOLIC DECREASE OF CHROMIUM(VI) MUTAGENICITY

was not significant, although it was very close to the 0.05 significance level, as evaluated by Student's t test.

Ability of Liver Microsomes from Variously Treated Rats in Metabolizing Mutagens in the Ames Test. The effects of the i.p. treatment of rats with the 3 enzyme inducers were also investigated by checking the ability of liver microsomes in affecting the mutagenicity of both promutagens and direct-acting mutagens (including dichromate) in the Ames test (Table 4).

The direct mutagenicity of sodium dichromate was decreased to the same extent by liver microsomes from untreated and from MC-treated rats. In agreement with the trends observed with liver S-12 fractions, the activity of liver microsomes was further amplified by PB and especially by AR treatment.

The mutagenicity of 4NQO was also decreased in the presence of liver microsomes, a process which was slightly enhanced by PB and MC and, more efficiently, by AR. All 3 inducers stimulated the metabolic deactivation of ICR 191, with the following rank of efficiency: AR > MC > PB.

Of the 3 procarcinogens tested, BP and AFB1 could not be activated by liver microsomes from untreated rats. Activation to mutagenic metabolites required induction with AR (both BP and AFB1), MC (BP only), or PB (AFB1 only). 2AF showed inducibility patterns similar to those of AFB1, but an evident activation was also afforded by microsomes from untreated and MC-treated rats.

DISCUSSION

All the metabolic systems tested led to reduction of the mutagenicity of sodium dichromate in the Ames test. As also confirmed in this study with calcium chromate and chromium trioxide, a similar trend is shared by a number of chromium(VI) compounds (2, 6, 7, 25, 26), and therefore, it appears to be a common property attributable to the hexavalent ionic species of this element. The observed efficiency of liver, kidney, and lung preparations is also consistent with the already reported rank of ability of S-9 fractions from rat tissues in lowering chromium(VI) mutagenicity, i.e., liver > adrenals > kidney > testis > stomach > lung, preparations from striated muscle, spleen, bladder, and colon being inactive (7, 25, 26).

The 2 studies reported in this paper agreed in demonstrating that the i.t. treatment of rats with high doses of dichromate (0.25 µg/kg) 5 times per week for 4 weeks, is capable of specifically enhancing the efficiency of lung preparations in decreasing the

mutagenicity of the same compound. In contrast, such treatment did not modify the reducing ability of liver S-12 fractions, presumably because, during transfer from the respiratory tract to other tissues, chromium(VI) is accumulated and reduced in erythrocytes (11, 23). Interestingly, the local stimulation that we have observed *in vivo* is in agreement with the reported increased tolerance of human cultured cells to potassium dichromate, following repeated *in vitro* exposures to the same salt (29).

Administration of 3 enzyme inducers; i.e., PB, MC, and AR, resulted in the expected changes (1, 4) in the concentrations and spectral properties of cytochromes P-450 in hepatic and pulmonary microsomes. Additionally, liver and lung S-12 fractions, as well as liver microsomal fractions, were found to selectively induce the metabolic activation or deactivation of known mutagens in the S. typhimurium test system. AR was the only one of these inducers which succeeded in stimulating reduction of chromium in the lung, although less effectively than in the liver. Chromium metabolism in hepatic microsomes was also induced by PB, which is in agreement with the conclusions of a study on the reduction of chromium(VI) by rat liver microsomal preparations (10). Our biochemical findings (9) provide evidence that an important role in chromium(VI) intracellular reduction is played by not only microsomal but also cytosolic components, including electron donors (e.g., GSH) and chiefly inducible enzyme activities. In particular, several lines of evidence support the view that DT-diaphorase, acting via a 2-electron transfer from reduced pyridine nucleotides (NADPH and NADH), may represent a key mechanism in the intracellular reduction of chromium(VI).

The interpretation of the results obtained in the present study and their possible relevance to the *in vivo* situation deserve some comments. Outside target cells, reduction of chromium(VI) is undoubtedly a beneficial mechanism, because chromium(III) is not capable of permeating mammalian cell membranes (17, 19) and is recognized to be inactive in cellular test systems (13, 14, 19, 26) and to be devoid of carcinogenic activity (13). On this ground, penetration of chromium(VI) entering the blood stream into erythrocytes and its subsequent reduction in these cells (11, 23) are consistent with the known lack of carcinogenicity of chromium at a distance from implant sites (13). Moreover, the daily reducing capacity of several mg of chromium(VI) by human saliva and gastric juice (26) is expected to constitute a very efficient barrier against the oral toxicity and carcinogenicity of this element.

It has been speculated that, after penetrating the cells as chromium(VI), a reduced form of it, such as chromium(V) (15) or chromium(III) (17, 19), might interact with DNA. In any case, irrespective of the form of chromium bound to DNA, the site of reduction inside the cell should represent a limiting factor for its availability to the genetic target (19). In particular, reduction in the cytoplasm (which can be mimicked *in vitro* by using various subcellular preparations, e.g., S-9 and S-12, cytosolic, and microsomal fractions) is likely to represent a detoxification phenomenon, due to trapping of the reduced species outside the cell nucleus. It is well known, for instance, that chromium(III) binds avidly a variety of cellular components (27). Such interpretation is consistent with the evidence that the ability of subcellular fractions from various tissues in reducing chromium(VI) is inversely related to the susceptibility of the same tissues as targets of chromium carcinogenicity. For instance, S-9 fractions from rat striated muscle, where experimentally injected chromium(VI) is carcinogenic (13), have no detectable reducing ability (23).

An intermediate situation can be postulated for the lung, which in humans is the only accepted target of chromium carcinogenicity (13, 14), yet with a broad variability of epidemiological and experimental data, which might reflect a variability in exposure levels as related to pulmonary defense mechanisms. In this respect, of particular interest are the results of an *i.t.* carcinogenicity assay with sodium dichromate,³ which was carried out in the same laboratory where the rats used in the present study were treated. Excepting for duration of treatments (30 months instead of 4 weeks), the treatment technique and schedule were identical in the 2 studies, and the same rat strain was used. In the carcinogenicity assay, tumor induction was only observed in the lungs, and dichromate was weakly carcinogenic only when administered once per week at 1.25 mg/kg. On the other hand, no cancer was induced in rats treated with the same frequency but at lower doses (0.25 or 0.05 mg/kg), nor in rats treated 5 times per week with equivalent total weekly doses (*i.e.*, 0.25, 0.05, and 0.01 mg/kg).

These patterns suggest that fractionated instillations of chromium(VI), even close to the maximum tolerated dose for a lifetime carcinogenicity study, can be detoxified more readily than a single massive dose, which may exceed lung defense mechanisms. The specific enhancement of chromium(VI)-reducing ability, observed in the present study using lung preparations from rats receiving 0.25 mg of dichromate per kg *i.t.* 5 times per week (but not in rats receiving 1.25 mg per kg once per week), is likely to represent a further defense mechanism against repeated exposures to chromium(VI) by the respiratory route. It may have also contributed to prevent carcinogenic effects in rats treated 5 times per week.

Therefore, also in the lung, the capability of chromium to interact with DNA and, presumably, to initiate cancer seems to depend on a quantitative balance between chromium(VI) entering the cell and its cytoplasmic reducing capacity. Under the experimental conditions of this paper and of its biochemical counterpart (9), it can be calculated that the post-mitochondrial components of the lungs of a rat would be capable, on the whole, of reducing hundreds of μg of chromium(VI) in 1 h. One should be very cautious in relating these figures, inferred from the *in vitro* efficiency of subcellular preparations, to the *in vivo* situation. However, it may be more than a coincidence that, in the carcinogenicity study,³ induction of tumors was observed only in a

small proportion of rats receiving *i.t.* doses of 250 to 500 μg of dichromate (*i.e.*, the single weekly administrations of 1.25 mg/kg) and that no induction was observed in those receiving doses of 50 to 120 μg (*i.e.*, the daily administrations of 0.25 mg/kg). Note that, as demonstrated in experiments with radiolabeled sodium dichromate, the *i.t.* administration of solutions of this salt results in a uniform distribution throughout the whole lung (28).

Several factors (some of which were identified in this study) can affect the magnitude of the observed detoxification processes, which renders questionable any attempt of extrapolating quantitative data to humans. Nevertheless, also considering that the capability of human lung S-9 fractions (from both cancer and noncancer patients) in reducing the mutagenicity of chromium(VI) is similar to the one observed with rat preparations (8), there seems to be sufficient evidence to support the conclusion that threshold phenomena, regulated by specific and inducible metabolic factors operating in pulmonary cells, are involved in the initiation of lung cancer by chromium. Additionally, the preliminary findings of a study that we have now in progress show that further inducible defense mechanisms against inhaled chromium are highly efficient in pulmonary alveolar macrophages.

ACKNOWLEDGMENTS

We thank Dr. Dieter Stenhoff (Institute of Toxicology of Bayer AG, Wuppertal, Federal Republic of Germany) for providing us with the treated rats used in this study.

Dr. Emil M. Mrak
Chancellor Emeritus
University House
University of California
Davis, California 95616 (#0004)

Dear Dr. Mrak:

I am writing on two counts:

1. To cry "foul" with regards to the scheduling of the September 26, 1985 Scientific Review Panel Meeting to discuss the ARB report on Chromium prior to our having received the revised document.
2. To point out that the Petrilli/DeFlora articles published in the journal Cancer Research should not have been considered a "bomb-shell" since I alerted you to their publication in my August 9, 1985 communication to you. As you may recall, you promised to forward my letter and attachments to ARB/DHS.

As to the first point, our group did not receive copies of SRP Public Meeting Notice or the Chromium draft report until the day of the meeting. In addition, a copy of the draft that I requested through ARB on September 18 did not arrive until October 4. I should also mention that in my telephone conversation with ARB personnel on the 18th, no mention was made of the September 26 SRP meeting.

In the way of further comment, I would like address specific responses as contained in Part C of the Draft Report that DHS made in reference to public comments it received on the Chromium Health Evaluation Document.

- 1) Comment V discusses the idea that the unit risk estimated from the Mancuso study is too high due to the omission of the exposure experience of highly exposed plant maintenance workers. DHS in its response applied its own estimates of maintenance worker exposure to recalculate the risk.

REC'D

Dr. Emil M. Mrak
University of California

Page 2

1) (Continued)

I would suggest that Allied, who made the original comments, would have a better feel for what a reasonable exposure level for maintenance workers employed in the chromate industry would be since they, like Diamond Shamrock Chemicals Company, were a producer of chromium chemicals at that time. Regardless, if DHS acknowledges the likelihood of a 3.5 fold underestimation of unit risk from the Mancuso data based on its own estimates of exposure, I believe that the unit risk should be adjusted accordingly. I would also point out that Allied's estimate of maintenance worker exposure levels indicated an exposure at 5-10 times that of the operators. The 3.5 fold DHS estimate utilized the low side of that exposure estimate; thus an additional correction is still appropriate to allow for underestimation of exposure.

2) Comment VII addressed the fact that several organizations submitting comments (Diamond Shamrock Chemicals Company among them) felt that data from a recent animal study and metabolism and/or detoxification studies along with the existence of published TLV's were supportive of a carcinogenic threshold for Cr(VI). The staff of DHS agreed that one interpretation of this information is consistent with the concept of a carcinogenic threshold. However, DHS, in its response, does not present other interpretations even though it implies there are. It also concludes that the information is not conclusive proof that a threshold exists.

In light of the recent work by Petrilli and DeFlora I feel that a case for a Cr(VI) carcinogenic threshold is stronger than ever. Conclusive proof in support of a carcinogenic threshold is unlikely, if not impossible, in that we are testing a hypothesis by demonstrating that a response (cancer) does not occur. Likewise, there is no conclusive proof to correlate exposure to hexavalent chromium at current ambient air levels with an increased cancer incidence rate either in man or animals.

Finally, to put things into a proper perspective the U.S. EPA, Office of Air and Radiation, Office of Policy, Planning and Evaluation in their July 1984 report "The Magnitude and Nature of the Air Toxics Problem in the United States" states that in 1983 there were 440,000 estimated cancer deaths (1900/million) based on 850,000 estimated incidences (3700/million).

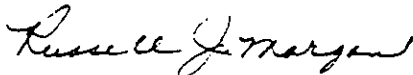

Dr. Emil M. Mrak
University of California
October 24, 1985
Page 3

Of these, 154,000 (670/million) were attributed to diet; 132,000 (570/million) to smoking; and 8,800 (38/million) to environmental pollution (about 2% of the total estimated cases). In addition, the report indicated that 3,000 to 14,000 cancer cases (13-61 incidences per million) were attributable to "passive smoking"; i.e. being around smokers. Contrasting these figures, the EPA report also estimated the cancer incidence rate for ambient level chromium based on three different studies to be 0.11, 0.29, and 1.05 incidences per million respectively.

It is questionable in my mind whether or not further regulation of chromium is justified. If, due to further restrictive regulation, the use of chromium in various application areas is displaced by inferior chromium substitutes, I could see the potential for loss of life associated with this action as being greater than the estimated incidence rate associated with that of cancer. For example, if the lead chromate pigment used in traffic paint and known for its brilliance, stability and hiding power were displaced with an inferior pigment, one could reasonably speculate that the loss of life due to increased highway traffic fatalities associated with this one change might equal the 3 to 25 cases of cancer per year which the EPA would estimate occur as a result of chromium exposure in the State of California. Similar arguments can be made for the other end use areas of chromium; i.e. production of alloys, use in refractories, metal finishing, wood treating, leather tanning, corrosion control, etc.

As always, thank you for the opportunity to express my personal views as well as the views of Diamond Shamrock Chemicals Company.

Sincerely,

Russell J. Morgan

P.O. BOX 2815
SANTA ANA, CA 92702

November 14, 1985

Mr. Russell J. Morgan
Diamond-Shamrock Chemicals Co.
P.O. Box 191
Painesville, OH 44077

Dear Mr. Morgan:

Your October 29 Letter to Dr. Mraz

Thank you for providing me with a copy of your comments on the revised health effects document on chromium. I have forwarded your letter to the Department of Health Services.

Regarding your receipt of the SRP Public Meeting Notice, we will send future notices regarding chromium to you directly. SRP Public Meeting Notices were sent on September 16, 1985 to Ms. Jill S. Barson of Diamond-Shamrock Corporation in Pasadena, Texas, and to Dr. J.B. Worthington of Diamond Shamrock Corporation in Dallas, Texas. Ms. Barson and Dr. Worthington will remain on our mailing list.

Your concern about regulation of chromium is understandable. Please recognize, however, that the identification of a substance as a toxic air contaminant is not in itself a restriction on the use of that substance. If a substance is identified by the Air Resources Board as a toxic air contaminant, a report on the need and appropriate degree of regulation for that substance will be prepared by the ARB staff, with the participation of Air Pollution Control (or Management) Districts and in consultation with affected sources and the interested public. The issues which the regulatory needs report shall address are described in Section 39665 of the California Health and Safety Code. I have enclosed a copy of the Chapter of the Code which includes that section. The issue of substitution of other materials for chromium, and any resulting potential impacts, will be addressed in the needs report, as described in Section 39665:

November 14, 1985

"(b) The report shall address all of the following issues, to the extent data can reasonably be made available: ...

(6) The availability, suitability, and relative efficacy of substitute compounds of a less hazardous nature.

(7) The potential adverse health, safety, or environmental impacts that may occur as a result of implementation of an airborne toxic control measure."

If hexavalent chromium is identified by the Board as a toxic air contaminant, we will welcome your participation in preparation of the regulatory needs report.

If you have questions concerning our regulatory program, or would like to discuss any of the issues you raised in your letter, please contact me at (916) 322-6023.

Sincerely,

William V. Loscutt, Chief
Toxic Pollutants Branch
Stationary Source Division
